Consider: Thousands of

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Burroughs Wellcome Co.
3030 Cornwallis Road
Research Triangle Park, NC 27709

Patients Rescued

WELLCOVORIN[®] TABLETS

== (leucovorin calcium) ==

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.¹

¹Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

Please see brief summary of prescribing information on next page.

WELLCOVORIN® TABLETS (leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B₁₂. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g., methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below $5 \times 10^{-8} M$.^{1,2}

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e., trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.^{3,4,5}

THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

**You can help us
raise the colorectal
cancer cure rate.**

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces
cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

for information contact:

Blenoxane[®] (sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane[®] be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma — Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas — Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma — Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary — This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of the lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain FI O₂ at concentrations approximately that of room air (25%) during surgery and the post-operative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions — In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes — These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other — Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban[®]. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

Coagulation Factor Deficient Human Plasma

- Substrate Quality
- Stable
- Fresh Frozen
- Mono-Specific

COAGULATION DEFICIENCIES AVAILABLE:

Factor I (Afibrinogenemia)	Factor IX	VonWillebrand Trait
Factor II	Factor X	(Mild and Severe)
Factor V	Factor XI	Prekallikrein
Factor VII	Factor XII	Kininogen (HMW)
Factor VIII	Factor XIII	Passovoy Trait
Factor VIII Inhibitor		Protein C

HEMATOLOGY PRODUCTS AVAILABLE:

Pooled Normal Plasma
Assayed Normal Plasma
Platelet Free Plasma

Aged Serum
Adsorbed Plasma
Coumadinized Plasma

- Plasmas are fresh frozen, citrated plasmas drawn from carefully screened HUMAN donors with congenital coagulation factor deficiencies.
- Shipments are packed in dry ice and usually delivered within 24 hours.
- Special arrangements are made to ship plasma in required volumes in vials (0.5 to 5.0 ml), in bags or on standing orders.

Today's IGV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens... in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).^{1*} Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.¹

IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.² With GAMIMUNE® N you get what you expect... IGV containing at least 98% pure gamma globulin.¹

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

Documented in vitro inactivation of HTLV-III virus[‡]

[‡]The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.³

"Native" IGIV

GAMIMUNE®N is manufactured without chemical modification. This means GAMIMUNE®N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.¹

Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE®N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE®N is affordable; there is no premium price for TODAY'S IGIV.

Artist's interpretation of blood platelets.

*It is not possible to predict which patients with ITP will respond to therapy.

¹In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days), transient (most often lasting from several days to several weeks) and should not be considered curative.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune® N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune® N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gamimune® N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood, there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune® N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune® N at a dose of 150 mg/kg body weight, following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune® N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune® N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune® N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune® N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune® N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune® N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune® N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune® N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune® N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune® N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune® N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PLA₁ alloimmune antibody with platelet anti-PLA₁ specificity) also responded to treatment with Gamimune® N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered, in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune® N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune® N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune® N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune® N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune® N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune® N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune® N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune® N. It is not known whether Gamimune® N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune® N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune® N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune® N. Symptoms reported with Gamimune® N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune® N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune® N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune® N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune® N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune® N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune® N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune® N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune® N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune® N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune® N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

TWO-COLOR ANALYSIS: COULTER HAS THE SOLUTION.

Our four new dual assays are ideal for reducing preparation and analysis time for screening panels in lymphocyte phenotyping. Selected combinations of monoclonal antibodies offer the maximum in clinical relevance, ease of use, and cost savings. We have available combinations for enumeration of T and B cells, helper/suppressor cells, helper cell subsets, and T3/13 for the identification of states of T lymphocyte activation.

- **OPTIMAL FORMULATIONS:** Proprietary manufacturing techniques yield clean results with little or no background.
- **CLINICALLY RELEVANT COMBINATIONS:** These particular dual color assays offer the most clinically relevant combinations.
- **MAJOR TIME SAVINGS:** Dual assays reduce overall technical labor time by half.
- **READY TO USE:** No centrifugation required for these liquid reagents, optimally titrated and conjugated.

To order, call 1-800-327-3778 or 1-800-432-6518, Ext. 6880 from Florida.

Chromogenics You Can Count On

The reasons your lab should use KabiVitrum chromogenics are as simple as 1 2 3...

The First

The substrates you've been using all along were developed first by KabiVitrum. They pioneered the development of synthetic chromogenic substrates 10 years ago, and revolutionized the investigation of coagulation and fibrinolysis proteins. Years of experience enables KabiVitrum to produce the highest quality substrates available.

The Most

KabiVitrum's extensive product line ranges from S-2251 — the most widely used substrate in the world — to new products for tissue plasminogen activator and inhibitor assays. As exclusive U.S. distributor of KabiVitrum products, Helena provides immediate shipment of your order from our Texas headquarters. And we back these products with solid support from our customer service group.

The Best

KabiVitrum is committed to continued development of new substrates. Some of the new substrates available are S-2366, for activated protein C and Factor XIa; and thrombin inhibitor, I-2581. Soon you can expect substrates for α_2 -macroglobulin, and α_1 -antitrypsin.

Call for your free KabiVitrum catalog, or to place an order. Toll free U.S.A. 800-231-5663.
In Texas, 800-392-3126.

In Alaska, Hawaii and Puerto Rico, 800-231-4678.

HELENA HAS THE ANSWERS

GRUNE & STRATTON, INC.

Required reading for all health care providers!

MALPRACTICE: A GUIDE TO AVOIDANCE AND TREATMENT

**Kenneth E. Brooten, Jr., Esq. and
Stuart Chapman**

This new text provides practical, in depth coverage about the avoidance and treatment of healthcare malpractice.

Malpractice: A Guide to Avoidance and Treatment presents practical, daily methods about how to avoid malpractice as well as pre and post trial procedures. Helpful guidelines on avoiding risks in the hospital, the do's and don'ts of prescribing, how to discharge patients, and the establishment of effective patient relationships, will aid the practitioner in the prevention of potential suits. Chapters describing the service of the summons, attorney selection, the anatomy of a trial, and case settlement help to familiarize the healthcare professional with each stage of a lawsuit. Malpractice checklists and forms add to the text's practical value.

Physicians, osteopaths, nurses, chiropractors, psychologists, and other health care providers, will find *Malpractice: A Guide to Avoidance and Treatment*, an indispensable, ready reference.

CONTENTS: Introduction. Acknowledgements. Dedications. Malpractice What Is It? Vicarious Liability. Establishing Effective Patient Relationships. The Role of the Consultant. The Do's and Don'ts of Prescribing. Avoiding Risks in the Hospital. The Medical Record. How to Discharge a Patient. Service of Summons. Selecting Your Defense Attorney. The Plaintiff's Attorney. Pre-Trial Procedures. The Expert Witness. The Anatomy of a Trial. When to Settle a Case. Post Trial-After The War is Over. Malpractice 2000.

Radiogenic mucositis or herpes simplex?

See answer under flap. ▶

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

When the problem begins with a virus,
end it with an antiviral.

The diagnostic
challenge in
immunocompromised
patients...

Please see following page for brief summary of prescribing information.

ZOVIRAX® I.V. (acyclovir sodium) STERILE POWDER/I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M² every 8 hours (750 mg/M²/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.^{1,2,3}

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.⁴

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.⁵

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.⁶

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS AND DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M²) over an hour was associated with a lower frequency—4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 5 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used

in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and LS178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonia, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.3 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 AND HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS — 5 mg/kg infused at a constant rate over 1 hour every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M² at a constant rate over 1 hour, every 8 hours (750 mg/M²/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M ²)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

PUZZLED ABOUT THOSE EXTRA REACTIONS? — The Answer . . . **MONOCLONALS**

New from Pel-Freez for Clinical and Basic Research, we have a large collection of Monoclonals (in excess of 200).

HUMAN LEUKOCYTES

B cells, T cells, (also activation markers),
Natural killer cells, Monocytes, Granulo-
cytes, Platelets (Gp Ib, Gp IIb-IIIa)

IMMUNOGLOBULINS

IgA, IgD, IgE, IgG subclasses, IgM, Lambda
and Kappa chains

HLA MOLECULES

Class I, Class II, B₂-Microglobulin

COAGULATION FACTORS

Factor VIII, Fibrinogen, Fibronectin, Thrombo-
spondin, Tissue Plasminogen Activator

BLOOD GROUPS

DIFFERENTIATION MARKERS ON HUMAN TISSUE

Keratin, Desmin, Villin, Vimentin, Neuro-
filament

PITUITARY HORMONES

HCG, FSH, LH, TSH, Prolactin, Thyro-
globulin, Leukemia cell markers

TUMOR MARKERS

Alpha Foeto Protein, Carcinoembryonic
Antigen

VIRAL ANTIGENS

STEROIDS AND OTHER HAPTENS

AND MORE

These monoclonals can be supplied as ascites fluid, or in fluoresceinated, biotinated or unconjugated forms.
Second step reagents are available for ELISA assays, immunocytochemistry and immunofluorescence.

For research use only

MONOCLONAL ANTI- ERYTHROPOIETIN NOW AFFINITY PURIFIED!

**Genzyme
Corporation proudly
announces a major
breakthrough in
erythropoietin
research...**

**Monoclonal anti-
Human Erythropoietin
(clone #AE7A5) is
now available!**

This antibody was raised against a 26 amino acid synthetic analogue peptide (see Sytkowski, A.J. and Fisher, J.W. (1985) J. Biol. Chem 260 14727). It recognizes an epitope within the first 26 amino acids at the NH₂-terminus of Human urinary and Human recombinant erythropoietin. The antibody cross-reacts with erythropoietin from rat but not sheep, baboon, or dog. It is not neutralizing, but is suitable for affinity purification with a dissociation constant of 6.7×10^{-9} M. The subclass is IgG2A.

The antibody is affinity purified using immobilized synthetic peptide and is 95%–98% pure. It is supplied as a 1 mg/ml solution in phosphate buffered saline.

The first troche treatment for oropharyngeal candidiasis.

Before treatment.¹

After treatment with MYCELEX Troche.¹

High clinical cure* rates.

A clinical cure rate of 96% was achieved in one randomized double-blind trial² in which MYCELEX Troche was administered to patients with oropharyngeal candidiasis. Other investigators have concluded that MYCELEX Troche "is highly effective treatment for chronic oral candidiasis."³

Dramatic improvement in symptoms.

Patients attain a high degree of relief at the end of therapy, as evidenced by the dramatic decrease in severity of glossitis, patches, perleche, pain, and other clinical signs and symptoms of thrush.⁴

Good patient acceptance, minimal side effects.

With MYCELEX Troche, messy suspensions and lengthy swishing are things of the past. MYCELEX Troche has a pleasant, slightly sweet taste. And an entire day's therapy—5 troches—can easily be carried in pocket or purse.

Based on a study of 52 episodes of oropharyngeal candidiasis, the investigators stated: "We believe that the troche form of clotrimazole...in the treatment of thrush in any patient population...is both effective and safe."^{2†}

*Clinical cure is defined as absence of signs and symptoms of the disease.

†See adjacent page for summary of prescribing information, including contraindications and adverse reactions.

Mycelex[®] Troche

(clotrimazole) 10 mg

The only troche for oropharyngeal candidiasis.

MYCELEX® (clotrimazole) TROCHE

Indications and Usage: Mycelex Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications: Mycelex Troches are contraindicated in patients who are hypersensitive to any of the components.

Warning: Mycelex Troches are not indicated for the treatment of systemic mycoses.

Precautions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches: elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with preexisting hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18-month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C: Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well-controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use: Safety and effectiveness of clotrimazole in children below the age of three years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).

Nausea and vomiting was reported in about one in 20 patients.

Dosage and Administration: Mycelex Troches are administered only as a lozenge that must be dissolved slowly in the mouth. The recommended dose is one troche five times a day for 14 consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short-term use, if possible.

How Supplied: Mycelex Troches—white, discoid, uncoated tablets are supplied in bottles of 70 and 140. Each tablet will be identified with the following: Miles 095.

Store below 86°F (30°C), avoid freezing.

INVITRON RESEARCH PRODUCTS INTRODUCES:

— rtPA —

A NEW STANDARD FOR tPA RESEARCH

Through the combination of proprietary genetic engineering techniques and patented large-scale perfusion bioreactor technology, Invitron scientists have developed a revolutionary process for manufacturing recombinant human tissue plasminogen activator (tPA). The tPA manufactured by this new process is characterized by very high purity, excellent *in vitro* enzymatic activity and most importantly, very high lot-to-lot consistency. INVITRON

RESEARCH PRODUCTS now offers recombinant human tPA for *in vitro* and laboratory animal research use only.

Product Availability:

- available in 2-chain form in the following vialled amounts as a liquid or active, carrier protein-free lyophilized product:
50 µg 1 mg 10 mg 50 mg
- customized buffering and aliquotting available for orders ranging in size from one gram to one kilogram
- larger quantities (multi Kg.) and one-chain form available upon request

Product Specifications:

- purity >95%
- activity approx. 500,000 IU/mg
- endotoxin <0.5 EU/mg

Representative of 2-Chain tPA

Reduced 10% SDS-PAGE

Gel Filtration Profile

Caution: For research use only in laboratory animals or *in vitro* testing. Not for diagnostic or human use. Not available for sale in the U.K. or Japan

REVIEW

The Coagulation-Kinin Pathway of Human Plasma

By Allen P. Kaplan and Michael Silverberg

INITIATION of the intrinsic coagulation-kinin pathway requires the interaction of certain negatively charged surfaces with three plasma proteins: factor XII (Hageman factor [HF]),¹ prekallikrein,^{2,4} and high-molecular weight (HMW) kininogen.⁵⁻⁷ Prekallikrein and HMW kininogen circulate in plasma as a complex with a 1:1 molar stoichiometry.⁸ These proteins bind to initiating surfaces, HF becomes activated, prekallikrein is converted to kallikrein, and HMW kininogen is digested to release the vasoactive peptide bradykinin (Fig 1). A second major plasma substrate of activated HF (HFa), factor XI, also circulates as a complex with HMW kininogen⁹ and is converted to factor XIa,¹⁰ which continues the intrinsic coagulation cascade. During the past 15 years, considerable progress has been made in elucidating the molecular details of these reactions. The aforementioned factors also interact with other plasma proteins, the peripheral vasculature, and with a variety of cell types to contribute to the body's inflammatory response. In addition, new methods have been developed to assess the contribution of this portion of the coagulation cascade to human disease. This review will include progress made in each of these areas, controversies that exist, and directions for future investigation.

INITIATION OF CONTACT ACTIVATION

Human HF, coagulation factor XII, is a single-chain β globulin of molecular weight 80,000.¹¹ During contact activation, HF becomes cleaved and then fragmented.^{12,13} The structural changes are accompanied by the development of enzymatic activity expressed against low-molecular weight (LMW) peptide derivatives as well as a number of plasma proteins. One paradox of contact activation is that kallikrein, the major plasma protease capable of activating HF¹⁴ (Fig 1) and other weaker activators (factor XIa and plasmin), are themselves formed in HF-dependent reactions.^{13,14} Purified HF and prekallikrein show minimal enzymatic activity if precautions are taken to eliminate contaminating active enzyme. However, when mixtures of HF and prekallikrein are exposed to an "activating" macromolecular anionic material (surface), rapid activation of both proteins takes place.

Any mechanism proposed for the initiation of contact activation must explain the behavior of normal and deficient plasmas. An important example is Fletcher trait plasma, which is deficient in prekallikrein^{2,4} and has a coagulation

defect that is corrected upon reconstitution with prekallikrein. If the time of incubation with surfaces is increased, the clotting time in a two-stage assay approaches that of normal plasma¹⁵⁻¹⁷; thus, surface-dependent activation of HF can occur in the absence of prekallikrein, and HFa can in turn convert factor XI to factor XIa so that coagulation can proceed. Little kinin is formed, however, because prekallikrein is absent (Fig 1). Small amounts of kinin may be made relatively slowly by direct cleavage of HMW kininogen by HFa¹⁸ or factor XIa, but the amounts are unlikely to be physiologically significant. In contrast, HF-deficient plasma does not activate upon contact with a surface. These observations draw attention to the central role of HF in contact activation; prekallikrein apparently plays an accelerating rather than a required role. This concept is supported by the discovery that human HF is able to autoactivate,^{19,20} a feature shared with the rabbit contact system²¹ but apparently not the bovine system.²² The autoactivation of HF may explain its activation in prekallikrein-deficient plasma and the consequent correction of the clotting defect.

The ability of HFa to cleave and activate native HF has been demonstrated directly for both rabbit²¹ and human proteins.^{20,23} In addition, the kinetics of the appearance of activity in purified HF exposed to a surface has been analyzed by an iterative computer model,²⁰ an explicit second-order kinetic model,²⁴ and by demonstration of exponential initial rates.^{25,26} All of these analyses have yielded data consistent with a simple autoactivation scheme in which HFa digests HF to produce more HFa.

The autoactivation of HF focuses our attention on the interaction of HF with a surface. This reaction poses the same dilemma as does the complete contact activation reaction in plasma; namely, how does one or more species of zymogen develop enzymatic activity when exposed to a

Fig 1. Schematic diagram of the contact activation pathway depicting HF autoactivation, activation of prekallikrein and factor XI, and the generation of bradykinin. The major cofactor role of HMW kininogen is on activation of HF substrates. Its direct role in HF activation by kallikrein is less clear and varies with the surface used and the milieu as described in the text.

charged but otherwise chemically inert surface. Hypotheses regarding the mechanism of initiation of contact activation may be divided into two categories. We can posit either that the surface amplifies traces of activity present in zymogen *ab initio* or that it functions in some manner to induce activity in previously inactive molecules. McMillin et al and Ratnoff and Saito originally proposed that HF undergoes a conformational change upon binding to a surface whereby it exposes or creates an active site that is then capable of activating prekallikrein.^{27,28} In this hypothesis, the induction of a low level of enzymatic activity precedes the observable cleavage of HF to make recognizable HFa.²⁸ The cleavage step occurs subsequent to kallikrein formation, and the latter enzyme acts upon HF in a feedback reaction. A further development of this hypothesis was proposed by Heimark et al²⁹ and by Kurachi et al³⁰ who observed rapid activation of prekallikrein and of factor XI by bovine HF and suggested that the initial rate of kallikrein formation was similar whether zymogen HF or HFa was used. These authors postulated that surface-bound HF was capable of a substrate-induced conformational change that created an efficient prekallikrein activator. This activity would not be detected by LMW peptide substrates that lack the macromolecular structures necessary to induce the conformational change.

Definitive proof of the creation of active sites prior to polypeptide chain cleavage is difficult to obtain. The reciprocal activations of HF and prekallikrein create a system with positive feedback that is therefore subject to rapid acceleration. Tankersley and Finlayson²⁵ estimated the kinetic constants for the component reactions and calculated that, at plasma concentrations of HF and prekallikrein, the introduction of a surface into the mixture where one molecule of active enzyme is present per milliliter ($5 \times 10^{-13}\%$ total protein) will result in 50% activation of either protein in 13 seconds. Such a low level of contamination of native HF with HFa has not been achieved; a level of 0.02% is the lowest thus far reported.³¹ Therefore, if native HF had no activity, rapid

activation of prekallikrein would be observed due to the HFa that is necessarily present.

Because human HF is able to autoactivate, low levels of HFa can accumulate in preparations of HF, even in the absence of a surface. Addition of irreversible inhibitors of active enzyme (eg, diisopropyl fluorophosphate, DFP) does not deplete active enzyme in a preparation much below 0.1%. We used a rapidly acting chloromethyl ketone inhibitor to try to destroy all traces of HFa in preparations of HF and thereby reduced enzymatic activity to less than 1/4,200 of that of HFa.³¹ Even after such treatment, HF was able to autoactivate and activate prekallikrein, albeit with very low initial rates. These experiments led to a proposal that the enzymatic activity of the zymogen (if any) is too low to measure and that the mechanism of contact activation of human plasma involved extremely low levels of active enzyme that are continuously present. That this might be possible *in vivo* is suggested by experiments in which prolonged incubation of purified HF with C1 esterase inhibitor (C1 INH) failed to prevent the conversion of HF to HFa or HF fragment (Hff).³² Therefore, the contact of plasma with a surface may induce "activation" by accelerating many 1,000-fold a normally occurring slow turnover of HF and prekallikrein. The effect of trace amounts of activity already present is amplified by the surface. The possibility that native HF does have trace activity analogous to the activity present in trypsinogen³³ is not excluded, although it is subject to the constraints of the aforementioned experiments. It should also be considered that the functioning of the contact system *in vivo* might require formation of trace quantities of HFa by other plasma enzymes, perhaps derived from cells.

There appear to be two components to the mechanism by which surface accelerates the reactions of contact activation. Griffin³⁴ demonstrated that the activation of HF by a series of different proteases was accelerated in the presence of a surface. He proposed that HF underwent a conformational change upon binding that increased its susceptibility to the cleavage leading to HFa formation. This observation suggests that surface-bound HF is a better substrate regardless of whether HFa (autoactivation) or kallikrein effects its cleavage and that this augmentation is one component of the catalytic action of the surface.

It is not known whether the cleavage and activation of surface-bound HF is accomplished by an enzyme molecule bound to a neighboring surface site or by one that remains free in solution. In the latter case, the catalytic effect of the surface would be due in large part to the creation of a local milieu in which the reversible binding of the protein components results in their increased concentration. Alternatively, the surface might physically locate the enzyme and the substrate in neighboring binding sites just as an enzyme does for its substrates. Another way to phrase this question is to ask whether both components of the Michaelis complex interact with the surface or only the substrate. Different mechanisms may be important for activation by HFa or kallikrein and with different surfaces.

Once a small amount of HFa has been produced, it converts prekallikrein to kallikrein,¹² the major plasma enzyme that activates HF.¹⁴ There is, therefore, reciprocal

activation in which these two proteins digest each other.³⁵ Because the rate of HF activation by kallikrein is much more rapid than HF activation by HFa,^{23,25} this pathway should be kinetically dominant. This conclusion is supported by studies of normal and prekallikrein-deficient plasma (Fig 1).

Recent evidence indicates that kallikrein also has to bind to the surface for maximum efficiency of HF activation. Thus, kallikrein cleaves surface-bound HF 3,000 times faster than fluid-phase HF, but cleavage by an equimolar quantity of the isolated (reduced and alkylated) light chain of kallikrein, which lacks the surface binding site,³⁶ is accelerated only 30-fold.³⁷ The activation of prekallikrein by HFa is also facilitated by surface, but to a lesser degree; in one study, dextran sulfate gave a 60-fold increase in cleavage by HFa and had no effect on the rate of cleavage by HFf.²⁵

It is pertinent at this point to consider the variety of compounds that have been used as surfaces. Much of the original work delineating the pathways of contact activation was done with kaolin. In terms of contact activation, however, kaolin is an ill-defined substance that is capable of binding many plasma proteins. More recently, dextran sulfate and sulfatide have been used as surfaces in studies of contact activation.^{24-26,30,31,38,39} These materials have the advantage of being much more homogeneous and, in the case of dextran sulfate, truly soluble. Using these activators, it has been possible to determine the rates of appearance of enzymatic activity and thereby to derive kinetic constants for the component reactions.^{24,25,37}

The idea of a reciprocal reaction between the zymogen and activated forms of HF and prekallikrein was complicated by the realization that there was yet another component required for optimal contact activation.^{40,41} Persons were studied whose plasma was not deficient in HF or prekallikrein, but their plasma gave very long kaolin-induced partial thromboplastin times (PTT) and generated no bradykinin. This led to the identification of HMW kininogen as a nonenzymatic cofactor that augments reciprocal activation.⁵⁻⁷ Initial experiments conducted with kaolin demonstrated that the presence of HMW kininogen increases the rate of conversion of prekallikrein to kallikrein by HFa and also increases the rate of activation of HF by kallikrein.^{42,43} HMW kininogen also increases the rate of factor XI activation by HFa.

One critical observation regarding the mechanism by which HMW kininogen functions as a cofactor was the demonstration that in plasma both prekallikrein⁸ and factor XI⁹ circulate bound to HMW kininogen and that these complexes bind to initiating surfaces via the HMW kininogen moiety.^{44,45} In plasma, HMW kininogen augments the attachment of prekallikrein and factor XI to surfaces such as kaolin^{44,45}; when the HMW kininogen is cleaved, this effect is augmented.^{46,47} Thus, HMW kininogen may be an activatable cofactor,⁴⁶ although the magnitude of this effect is uncertain. Adhesive glycoproteins such as fibrinogen may compete with HMW kininogen for binding to initiating surfaces. Studies have shown the presence of antigenic fibrinogen on clot-promoting surfaces that becomes undetectable after ten minutes of contact when HMW kininogen is present, an effect not observed in HMW kininogen-

deficient plasma.^{48,49} It will be of interest to determine whether cleaved and uncleaved HMW kininogen behave differently in such assays.

In buffer systems,⁴⁵ prekallikrein and factor XI bind to kaolin equally well in the presence or absence of HMW kininogen, but activation of each by HFa is dependent upon the presence of HMW kininogen. Aside from the quantitative binding effects seen in plasma, therefore, HMW kininogen must place the substrates of HFa in a conformation that facilitates their cleavage (Fig 2). More difficult to explain is the ability of HMW kininogen to augment the cleavage and activation of HF by kallikrein since it has no demonstrable effect upon the enzymatic activity of kallikrein (using synthetic substrates) and no known interaction with HF. The dissociation constant for the prekallikrein (kallikrein)-HMW kininogen complex is 15 nmol/L,^{50,51} and at plasma concentrations, about 10% to 20% of prekallikrein circulates free.^{8,50-53} Thus, kallikrein that is formed by activation of surface-bound prekallikrein-kininogen complexes can dissociate from the surface. It is then able to digest adjacent HF molecules on the same or other particles.^{45,54} In this fashion contact activation can be disseminated along the surface (Fig 2). Thus, the effective concentration ratio of kallikrein/HF is increased in the presence of HMW kininogen, which may account for the augmentation.

In contrast to these observations are studies of the human contact activation system that have been done with purified HF and prekallikrein by using dextran sulfate or sulfatide as activators. Under these conditions, both HF and prekallikrein are rapidly activated in the absence of HMW kininogen.^{24,25,31,37,55} The cofactor produces a small acceleration in the activation of HF by kallikrein,⁵⁵ whereas its effect on the reverse reaction has not been reported. This contrasts with activation in the presence of kaolin in which activation of prekallikrein by HFa is strongly dependent on HMW kininogen.⁴⁵ When dextran sulfate is added to plasma, however, almost no kallikrein is produced if HMW kininogen is absent.⁵⁶ Thus, the effects of a surface vis-à-vis the role of HMW kininogen differ somewhat depending upon the nature of the surface used and whether the reaction is studied in plasma or with purified components.

One way in which a plasma milieu might be different relates to observations that HMW kininogen may protect

Fig 2. Hypothetical depiction of surface binding of HF (factor XII) and complexes of HMW kininogen (HMW-K) with prekallikrein or factor XI. Kallikrein dissociation to facilitate factor XII activation on the same or adjacent particles is shown by dashed lines.

kallikrein^{57,58} and factor XIa⁵⁹ from inhibition by C1 INH, α_2 macroglobulin, and α_1 antitrypsin and thereby augment the plasma half-life of each enzyme. The light chain of HMW kininogen, the portion of the protein that binds to prekallikrein and factor XI,⁶⁰ was reported to be as effective in preventing the inhibition as intact HMW kininogen. This result suggested that the phenomenon cannot be explained by substrate competition between HMW kininogen and C1 INH at the active site of kallikrein.⁵⁸ This is a controversial point, and Van der Graaf et al observed no effect of HMW kininogen upon inhibition of kallikrein by C1 INH.⁶¹ We found the second-order rate constant for the reaction of kallikrein with C1 INH to be unchanged in the presence of a saturating concentration of kinin-free HMW kininogen.⁶² Therefore, we are unsure whether HMW kininogen protection of enzyme inactivation contributes significantly to its augmentation of contact activation.

CLEAVAGE OF PROTEINS DURING CONTACT ACTIVATION

Figures 3 to 5 diagram the cleavages and fragments resulting from activation of each component of the system and indicate functional domains where they have been defined. HF (Fig 3) is initially cleaved within a disulfide bridge so that a single chain of 80,000 is converted to a two-chain enzyme in which a heavy chain of 50,000 is disulfide linked to a light chain of 28,000.¹⁷ No loss in size results, and the enzyme is called HFa (or α HFa). The binding site for the surface is on the heavy chain,⁶³ and the light chain contains the active enzymatic site. Further cleavage by kallikrein digests HFa at two sites (2 and 3) in sequence²³ to form HFf (or β HFa) in which a heavy chain of 28,000 is disulfide linked to a light chain of either 2,500 or 500.⁶⁴ A mixture of these two forms accounts for the doublet typically seen in alkaline disk gels¹² or unreduced sodium dodecyl sulfate (SDS) gels.¹⁷

Enzymes other than kallikrein are able to cleave and activate HF, including plasmin^{13,34,65} and factor XIa,¹⁴ but

Fig 3. Sites of cleavage of HF during contact activation. Site 1, within a disulfide bridge, converts HF to HFa. Cleavage external to the disulfide bond at sites 2 and then 3 converts HFa to the two forms of HF. The light chain of HFf (residues 334 to 353 or 343 to 353) is derived from the C-terminal end of the heavy chain of HFa. Since the surface binding site is at the amino terminal end of HF or HFa, formation of HFf leads to dissociation from the surface. The active-site charge-relay complex (His, Asp, Ser) is at the C-terminal end.

Fig 4. Diagrammatic representation of the activation of prekallikrein and factor XI by HFa. Cleavages occur within disulfide bridges in each case, and the active site is in the light chain(s). Because factor XI is dimeric, factor XIa has two identical active sites.

these reactions are less efficient. The cleavage of HF by HFa during autoactivation is of potentially greater significance than these reactions. Autoactivation produces, in addition to HFa and HFf, a third form in which the serine protease domain is linked to a 12,000-MW fragment of heavy chain to give a molecule of MW 40,000 before reduction^{13,23} (Fig 3), but kallikrein rapidly converts it to HFf.

The complete amino acid sequences of the heavy chain of HFa⁶⁶ and both chains of HFf⁶⁷ are now known. Fujikawa and McMullen⁶⁷ found nine amino acids in the light chain of HFf, presumably corresponding to the short segment remaining after cleavage at site 3. The heavy chain possesses a variety of structural domains with homology to other proteins. Two short domains resemble fibronectin, two growth factor regions are homologous with epidermal growth factor, and a kringle structure is seen, as has been reported in plasminogen, tissue plasminogen activator, urokinase, and prothrombin. The light chain of HFa (or heavy chain of HFf) containing the active site has a high degree of homology with tissue plasminogen activator and progressively less homology

Fig 5. Depiction of the structure of human HMW kininogen and the consequences of cleavages at these sites. The amino terminal portion (heavy chain of cleaved kininogen) is a cysteine protease inhibitor; the light chain of cleaved HMW kininogen serves as the cofactor function in coagulation.

with urokinase, plasmin, trypsin, factor X, or factor IX. Strong homology with proteins involved in fibrinolysis is apparent. More recently, the complete amino acid sequence has been deduced by using factor XII cDNA isolated from a c-DNA library prepared from human liver mRNA.⁶⁸

Hff lacks the binding site for the surface and, once formed, is released into the fluid phase. It is not a coagulation factor since factor XI activation is strictly surface dependent⁶⁹; Hff possesses only 2% to 5% of the coagulant activity of HFa.^{12,13} Hff is an effective prekallikrein activator,^{12,13,69} however, and can lead to bradykinin formation until C1 INH binds and inactivates it.^{70,71}

Prekallikrein is a single chain γ globulin (isoelectric point [IEP] 8.9) with two forms at MW 85,000 and 88,000,⁷² both of which are present in all plasmas tested. As many as seven forms can be identified by isoelectric focusing.⁷³ Prekallikrein is converted to kallikrein (Fig 4) by cleavage within a disulfide bridge such that a heavy chain of 52,000 is disulfide linked to light chains of either 33,000 or 36,000 (one for each molecular form).^{72,74} The heavy chain interacts with the surface and binds to HMW kininogen,³⁶ whereas the light chain has the enzymatic active site.⁷² Purified light chain retains enzymatic activity on synthetic substrates³⁶ or in fluid-phase kinin generation but is ineffective as a surface-dependent coagulation factor. During lengthy incubations, the heavy chain of kallikrein is further cleaved so that a kallikrein of lower MW results (β -kallikrein), with little loss in kinin-forming ability; but activation of other proinflammatory actions (discussed subsequently) are altered.⁷⁵

Factor XI is unusual among coagulation factors because it consists of two identical disulfide-linked chains^{76,77} (Fig 4). Upon activation each chain is cleaved to yield disulfide-linked heavy and light chains; therefore, the active enzyme has four chains. The heavy chains bind to the surface.⁷⁸ Each light chain has an active site⁷⁹ and, when inactivated, can bind 1 mol of inhibitor.⁷⁷ Also, it has recently been shown that the molar ratio of binding of HMW kininogen to factor XI is 2:1.⁸⁰

HMW kininogen is cleaved by plasma kallikrein at two sites (Lys-Arg and Arg-Ser) to liberate the nonapeptide bradykinin. Both cleavages occur within a disulfide bridge⁸¹⁻⁸³ so that kinin-free HMW kininogen consists of a heavy chain of MW 62,000 disulfide linked to a light chain variously reported as having an MW of 56,000 to 62,000.^{46,50,84-87} It is unclear whether release of bradykinin results in chains that are equal in size (by SDS-polyacrylamide gel electrophoresis) and that another cleavage follows that forms the 56,000 band or whether the size differences reported in these studies are due to differences in technique. Further proteolysis of the light chain by kallikrein converts it to a light chain of 45 to 47,000.^{81,83,84} The heavy chain of HMW kininogen, which is identical to the heavy chain of LMW kininogen,^{81,88,89} has been shown to inhibit cysteine proteases⁹⁰⁻⁹² such as cathepsin L, papain, or platelet calpain 2.⁹³ In fact, cDNA analysis of α_2 thiol proteinase inhibitor demonstrates that it is identical to LMW kininogen.⁹¹ The light chain of HMW kininogen is the coagulant portion of the molecule^{60,81} and possesses a binding site for the surface⁹⁴ as well as a binding site for the heavy chain of prekallikrein^{8,51,52,60,95} or factor XI^{9,60,96} (Fig

5). These binding constants are estimated to be 3.4×10^7 mol/L⁻¹ and 4.2×10^8 mol/L⁻¹, respectively.⁶⁰

Human LMW kininogen is identical to HMW kininogen from the amino-terminus to 12 residues beyond the bradykinin moiety.⁹⁷ During transcription of kininogens the DNA corresponding to this segment can be spliced into two different DNA segments, which correspond to the kininogen light chains⁸⁹ (Fig 6). Those latter segments are completely different in terms of size, amino acid sequence, and function. LMW kininogen has no procoagulant activity and no known interaction with other proteins of the contact activation system, and the function of its light chain (if any) is unknown.

Bovine HMW kininogen has an additional kallikrein cleavage site located beyond the bradykinin moiety in a region that would correspond to the amino-terminal segment for the human HMW kininogen light chain. Cleavage at this site results in the loss of a fragment (termed fragment 1.2),⁹⁸⁻¹⁰⁰ which appears to contain the binding site for the surface.⁹⁴ Its removal thus destroys the coagulant cofactor activity.¹⁰⁰ The species difference may be attributable to the presence of a 22-residue sequence in the human but not the bovine protein and the presence of Lys rather than Arg at the site of the human protein analogous to the carboxy-terminus of bovine fragment 1.2.¹⁰¹ In humans, factor XIa performs a similar cleavage in the HMW kininogen light chain, which likewise inactivates it¹⁰² and may represent an intrinsic control mechanism.

The major kininogen of rodents is T kininogen from which a kinin (Ile-Ser-bradykinin) is cleaved by high concentrations of trypsin or cathepsin D¹⁰³ but not by kallikreins. The proteins corresponding to HMW and LMW kininogens are present but are minor components; all three kininogens are strongly homologous at the DNA and amino acid sequence level.¹⁰⁴

THE INTRINSIC FIBRINOLYTIC PATHWAY

An HF-dependent pathway leading to the conversion of plasminogen to plasmin was described in the 1960s and early 1970s.¹⁰⁵⁻¹⁰⁷ A defect in this pathway has been observed in plasma deficient in either HF, prekallikrein, or HMW kininogen.²⁻⁷ This is a relatively weak fibrinolytic pathway, and it is difficult to demonstrate in whole plasma because it does not lead to formation of large quantities of a potent plasminogen activator. Relatively small quantities of plasmin are generated, and the plasmin is then rapidly inacti-

Fig 6. Diagram of the structure of the gene for the kininogens. A potential splicing site is located just beyond the bradykinin. If the DNA is read through this region, HMW kininogen m-RNA results. If the alternative splicing site and more distal exon is attached, LMW kininogen mRNA is formed.

vated by plasma inhibitors. Therefore, most of the aforementioned studies utilized diluted acidified plasma in which inhibition of both contact activation and plasmin are minimized and fibrinolytic activity can be measured. Although the identification of the plasminogen activator in this pathway has proved to be particularly difficult, certain aspects of the abnormal behavior of various deficient plasmas are predictable, given that HF is required. Prekallikrein and HMW kininogen are needed for optimal HF activation, and HMW kininogen is required for activation of both prekallikrein and factor XI; therefore, a deficiency of any of these proteins will be associated with abnormal intrinsic fibrinolysis.

By utilizing purified components, kallikrein was first shown to be a plasminogen activator.¹⁰⁸ A plasminogen proactivator was described subsequently that appeared to differ from prekallikrein¹⁰⁹; the activity was demonstrable in prekallikrein-deficient plasma.¹¹⁰ Others disagreed, reporting that plasminogen proactivator and prekallikrein were identical.^{111,112} Later studies, however, demonstrated that a plasminogen proactivator could be identified in the γ globulin fraction of prekallikrein-deficient plasma and was identified as factor XI.⁷² When compared, kallikrein and factor XIa were found to be equipotent as plasminogen activators.¹¹³ The concentration of prekallikrein, however, is much greater than factor XI (six- to tenfold); kallikrein can dissociate from surfaces into the fluid phase, whereas factor XIa does not, and prekallikrein can be activated in the fluid phase by HFF. Therefore, kallikrein appears to be more important than factor XIa as a plasminogen activator although one can demonstrate a fibrinolytic abnormality in factor XI-deficient plasma.¹¹⁴ The potency of both kallikrein and factor XIa on a molar basis is, however, many thousand-fold less than urokinase.^{113,115,116} Activated HF (HFa or HFF) also can convert plasminogen to plasmin directly,¹¹⁷ but it is only about 5% as potent as kallikrein.¹¹³ These are all weak reactions, and one can readily argue that plasminogen is not a significant substrate for any of these enzymes. It is interesting to note, however, that direct incubation of factors VIIa, IXa, Xa, or thrombin with plasminogen fails to generate plasmin at any concentration tested. Of the coagulation factors, then, only proteins of the contact activation system catalyze the conversion of plasminogen to plasmin. More recently, there have been reports that kallikrein can activate the trace of prourokinase present in plasma¹¹⁸ and urokinase might then be the major plasminogen activator.¹¹⁹ Inhibition by antiurokinase antibodies supports this notion,¹²⁰ whereas others disagree.^{120a} Nevertheless, the quantity of urokinase generated is very small. The effects of both C1 INH and α_2 antiplasmin may be abrogated by the addition of certain organic compounds (eg, flufenamic acid derivatives) to plasma.^{121,122} Contact activation of plasma treated in this way results in the formation of only about 35 ng/mL of plasmin¹²¹ (Fig 7).

INTERACTION WITH OTHER PLASMA PROTEASES AND WITH CELLS

HFa has been reported to activate factor VII^{123,124} and thereby initiate the extrinsic coagulation pathway. This

Fig 7. Interaction of proteins of contact activation with other plasma proteolytic cascades. HFF can initiate activation of the classic complement pathway, whereas kallikrein can convert prorenin to renin and participate in intrinsic fibrinolysis. Kallikrein, factor XIa, and HFa can all directly convert plasminogen to plasmin. Kallikrein can also convert single-chain urokinase (termed prourokinase; this is an active enzyme that is normally inhibited in plasma by a competitive inhibitor) to two-chain urokinase (which transiently escapes inhibition). Whether this urokinase is the major plasminogen activator or whether it is the direct effect of kallikrein is uncertain.

contributes minimally to the kaolin-activated PTT as usually performed, but it is responsible for the shortened clotting time seen when plasma is exposed to the cold.^{125,126} This is accentuated in women who use oral contraceptives containing estrogen, apparently due to an increased concentration of HF.¹²⁷⁻¹²⁹ It is theorized that this pathway might contribute to the increased incidence of thrombosis reported as a complication of oral contraceptive use.

HFF (but not HFa) has been shown to activate enzymatically the first component of complement¹³⁰ when it is incubated with purified C1 or added to plasma (Fig 7). C1 activation is due to cleavage of the C1r subcomponent¹³¹ by HFF. Little complement activation is seen, however, when kaolin is incubated with whole plasma. Significant complement activation may be seen only in conditions that result in substantial conversion of HFa to HFF. One such circumstance is C1 INH deficiency (ie, hereditary angioedema) in which HF activation may contribute to complement consumption.^{132,133} Kallikrein can also cleave C1 subcomponents, but the net result is destruction rather than activation. On the other hand, kallikrein can activate factor B of the alternative complement pathway and thereby substitute for factor D.¹³⁴

Kallikrein has been reported to interact with human leukocytes in a variety of ways. It is a chemotactic factor for neutrophils¹³⁵ and monocytes,¹³⁶ and it has been shown to cause neutrophil aggregation¹³⁷ and release of elastase.¹³⁸ In a rabbit model, kallikrein stimulation of chemotaxis appeared to require cleavage of C5 and release of C5a chemotactic factor.¹³⁹ It is therefore possible that C5 bound to the surface of neutrophils is being cleaved in the aforementioned reactions. However, antikallikrein serum was inhibitory whereas anti-C5 serum had no effect; the authors therefore concluded that the effect of kallikrein on human neutrophils is independent of complement. Further, a degraded form of kallikrein (β -kallikrein) in which the heavy

chain is partially digested is enzymatically active on kininogen to form kinin, but its reactivity with neutrophils is markedly attenuated.¹⁴⁰ HFa (but not HFF) has also been shown to stimulate neutrophils; a requirement for a binding site in the heavy chain appeared to be required for the reaction to proceed.¹⁴¹ There are no studies demonstrating either a cell surface receptor for these enzymes or required cleavage of surface components. In each instance, however, the active site of the enzyme is required so that the proenzyme or DFP-treated enzyme is inactive.^{135,137}

The components of the contact activation system also appear to interact with platelets. There are apparently separate platelet receptors for plasma factor XI and factor XIa.¹⁴² Platelets also have intrinsic factor XI activity that differs from plasma factor XI in MW and isoelectric point but that cross-reacts with it immunologically. This activity is present in patients who are deficient in plasma factor XI.^{143,144} Platelet-associated factor XI can be activated by both HF-dependent and -independent mechanisms.¹⁴⁵ The membrane of activated platelets also appears to provide a surface on which HF can be activated, a process dependent on prekallikrein and HMW kininogen,¹⁴⁵ so that bound factor XI is then activated. HMW kininogen demonstrates binding to platelets^{146,147} that is zinc dependent.^{147a} It has been shown to be present within the alpha granules of platelets,¹⁴⁷ becomes available during platelet activation,¹⁴⁸ and augments binding of factor XIa.¹⁴² Yet it is clear that platelets are not requisite for contact activation as they are for later steps in coagulation. Therefore, contact activation proceeds normally in platelet-poor plasma, and the addition of platelets provides little or no augmentation. In fact, there is evidence that platelets may actually inhibit prekallikrein and factor XII activation by secretion of β thromboglobulin^{148a,148b}; however, platelet activation in peripheral tissues due to injury and/or localized thrombosis may contribute to contact activation and local kinin formation. In some circumstances the platelets may also provide a factor XII bypass in contact activation.¹⁴⁹

CONTROL MECHANISMS

Regulation of the HF pathways occurs by both intrinsic and extrinsic mechanisms. Cleavage of HFa to HFF is one example of an intrinsic control in which coagulation via the surface-dependent activation of factor XI is limited whereas bradykinin generation via fluid-phase activation of prekallikrein continues. Likewise, the digestion of kinin-free HMW kininogen light chain by factor XIa limits its coagulant activity.¹⁰² Extrinsic controls are provided by plasma inhibitors of each enzyme (Table 1). The only major plasma inhibitor of HFa or HFF is C1 INH.^{70,71,150,151} There are two main kallikrein inhibitors in plasma: α_2 macroglobulin¹⁵² and C1 INH.^{153,154} When kallikrein is added to plasma, approximately half is bound to each inhibitor at equilibrium.^{155,156} When a surface such as kaolin is added to plasma, however, close to 70% or 80% of the kallikrein formed is bound to C1 INH¹⁵⁷; the mechanism responsible for this change in inhibition ratio is unknown. Factor XIa is inhibited primarily by α_1 antitrypsin^{59,158} and C1 INH,¹⁵⁰ whereas plasmin is inhibited by α_2 antiplasmin¹⁵⁹⁻¹⁶² and α_2 macroglobulin.¹⁶³⁻¹⁶⁵ Anti-

Table 1. Major Inhibitors of Active Proteases of the Contact Activation System

Enzyme	Inhibitor
HFa (HFF)	C1 INH
Factor XIa	α_1 Antitrypsin, C1 INH
Kallikrein	C1 INH, α_2 macroglobulin
Plasmin	α_2 Antiplasmin, α_2 macroglobulin

thrombin III (AT III) accounts for only a few percent of plasma inhibition of each of these factors,¹⁶⁶⁻¹⁷¹ but its contribution in the presence of heparin is uncertain. There is clearly less augmentation than is seen with thrombin. Some studies have revealed little augmentation of AT III inhibition of HFa,^{71,151,172} kallikrein,¹⁷³ or factor XIa¹⁷⁴ in the presence of heparin, whereas others find that heparin has a prominent effect upon the rate of AT III inhibition of each of them.^{168,171,175} These reactions need to be reassessed with purified components and the rate of inhibition of each enzyme carefully determined in heparinized *v* citrated plasma. For such studies the dose of heparin and definition of the activity of the fraction used will be critical.

Bradykinin is an exceedingly potent vasoactive peptide that can cause venular dilatation, increased vascular permeability, hypotension, constriction of uterine and gastrointestinal (GI) smooth muscle, constriction of coronary and pulmonary vasculature, bronchoconstriction, and activation of phospholipase A₂ to augment arachidonic acid mobilization. Its regulation is of prime importance, and plasma contains a variety of enzymes that serve this function. Recent studies of kinin degradation from our laboratory are summarized in Fig 8. First, the C-terminal arginine is removed by carboxypeptidase N,^{176,177} thereby leaving the residual octapeptide. The des-Arg⁹-bradykinin formed is inactive in the skin or GI tract, but it is equipotent to bradykinin in causing hypotension.¹⁷⁸ Separate receptors for these two moieties have been proposed and are called B₁ (des-Arg⁹-bradykinin) and B₂ (bradykinin).¹⁷⁹ The rate of Arg removal in serum, however, far exceeds the rate in plasma,¹⁸⁰ whereas the level of carboxypeptidase N is unaltered. It appears that a carboxypeptidase B-like enzyme is generated during coagulation¹⁸⁰ that is secreted, perhaps, by platelets or neutrophils. Des-Arg⁹-bradykinin is then degraded by angiotensin-converting enzyme to the pentapeptide Arg-Pro-Pro-Gly-Phe plus the tripeptide Ser-Pro-Phe.¹⁸¹ The C-terminal phenylalanine is then cleaved from each peptide by enzymes possessing

Fig 8. Pathway for degradation of bradykinin in human plasma. One or more carboxypeptidases remove the C-terminal arginine, and des-Arg⁹-bradykinin is cleaved by angiotensin-converting enzyme (ACE). The pentapeptide and tripeptide products are further degraded by enzymes (not yet characterized) with activities resembling carboxypeptidase A and/or a prolylcarboxypeptidase.

activities consistent with carboxypeptidase A and prolylcarboxypeptidase, respectively.¹⁸⁰ These enzymes have not yet been isolated or characterized. Not shown in Fig 8 is the further clearance of Arg-Pro-Pro-Gly and Ser-Pro so that the final degradation products of bradykinin digestion are Arg-Pro-Pro-Gly and free amino acids.

Because bradykinin is a peripheral vasodilator, it has been considered to act as a potential "counterbalance" to the vasopressant effects of angiotensin II. From the previous discussion, it is clear that these two peptides are also related in terms of metabolic control since angiotensin-converting enzyme cleaves the decapeptide angiotensin I to generate angiotensin II and also degrades and inactivates bradykinin or des-Arg⁹-bradykinin. It is important to point out that although angiotensin-converting enzyme readily degrades bradykinin in physiological buffers,¹⁸² bradykinin is first converted to des-Arg⁹-bradykinin in plasma or serum and the latter peptide is actually the substrate for the converting enzyme.

There are other interactions of the kallikrein/kinin system and the renin/angiotensin system in plasma and serum that have been described. For example, plasma kallikrein has been shown to convert prorenin to renin (Fig 7)^{183,184}; when plasma is acidified and then neutralized, prorenin is converted to renin, and the latter alkaline phase is an HF-dependent reaction. It appears that acidification negates the effects of plasma inhibitors and affects prorenin susceptibility to activation. The importance of this reaction under normal physiological conditions is uncertain.^{185,186,186a}

ASSESSMENT OF CONTACT ACTIVATION IN HUMAN DISEASE

The HF-dependent pathways described herein are not likely to contribute to thrombosis and hemostasis in a major way. Thus, although activation of HF leads to *in vitro* coagulation, in most thrombotic disorders there is activation of the extrinsic pathway occurring either alone or in addition to HF activation, and the effects of tissue factor predominate. Certainly, there is no thrombosis associated with hereditary angioedema, a disorder in which contact activation is prominent. Likewise, patients deficient in HF, prekallikrein, and HMW kininogen have no obvious bleeding diathesis, and factor XI-deficient patients have a bleeding disorder that is highly variable and often mild. Observations such as these have led to considerations of physiological mechanisms of factor XI activation that bypass the other contact activation components, but these remain unsettled. Most evidence suggests that the importance of the cascade relates to the pathogenesis of inflammatory reactions, the local control of blood flow (in which bradykinin functions as a hormone), and perhaps control of BP. To assess the HF-dependent pathways in human disease, we ideally would like to measure each active enzyme, demonstrate cleaved HMW kininogen, and assay bradykinin. These determinations are limited because the enzymes and the bradykinin are rapidly inactivated, and often one has to determine the level of residual proenzyme. One can quantitate HF, prekallikrein, or HMW kininogen in plasma by coagulant assay,¹⁸⁷ immunologic determination of antigen levels,^{53,188,189} or by *in vitro* activa-

tion and evolution of enzymatic activity.^{38,190-192} Shifts in electrophoretic mobility are indicative of complex formation between enzymes and their inhibitors and provide qualitative evidence that activation has occurred. Thus far monoclonal antibodies that react solely with the active site of enzymes have not been developed, although De Agostini et al¹⁹³ have described a monoclonal antibody that reacts with a neoantigen in the kallikrein-C1 INH complex.

The previously described assays are useful if sufficient activation has occurred to cause significant depletion of substrate. But if only a small amount of each factor is converted, it may be missed. Assays have recently been developed for enzyme-inhibitor complexes based on the assay for plasmin- α_2 antiplasmin complexes by Harpel.¹⁹⁴ These include double-antibody enzyme-linked immunosorbent assay methods for HFa-C1 INH,¹⁹⁵ kallikrein-C1 INH,¹⁹⁶ and kallikrein- α_2 macroglobulin complexes,¹⁹⁷ which can detect as little as 1% activation of any of the components. Bradykinin¹⁹⁷ and des-Arg⁹-bradykinin¹⁹⁸ can be determined by radioimmunoassay.

These latter assays have just begun to be applied to disease states; most of the literature describes results obtained with earlier methods. Hereditary angioedema receives considerable attention because C1 INH is absent and there is simultaneous activation of the HF-dependent pathways and the classic complement pathways. Patients present with episodic swelling occurring virtually anywhere in the body, attacks of severe abdominal pain due to edema of the bowel wall, and laryngeal edema. Although a kinin derived from a cleavage product of the second complement component was thought to be responsible for the edema,¹⁹⁹ other studies suggest that bradykinin is the critical peptide.^{133,200} On the other hand, a kininlike vasoactive substance may yet be shown to be a complement derivative, as shown by recent reports.^{200a} During attacks of angioedema there is depletion of prekallikrein and HMW kininogen²⁰¹ and formation of bradykinin,²⁰² and blisters induced in the skin of patients are found to have elevated plasma kallikrein levels.²⁰³ The complement activation appears due to autoactivation of C1 (specifically C1r) in the absence of C1 INH,^{204,205} but this may be augmented by HFF,^{130,131} particularly during acute attacks of swelling.

Aside from hereditary angioedema, there is a relatively large amount of literature demonstrating activation of the HF-dependent pathways in plasma or serum in a wide variety of inflammatory disorders; in some disorders, the activation is coincident with the patients' symptoms. There are no data, however, that prove that the consequences of such activation lead to disease manifestations or the converse, that inhibition of the pathway will ameliorate symptoms. These should be viewed as promising associations and are important areas for future investigation. These will only be briefly described.

Contact activation may occur during allergic diseases, for example, nasal washings of patients with allergic rhinitis who have been challenged with antigen contain lysyl bradykinin, bradykinin, kininogen, and kallikreins derived from mast cells and plasma.²⁰⁶⁻²⁰⁹ The latter may represent contact activation on a surface altered by the initial inflammation.

Other possibilities for activation might include negatively charged macromolecules in mucosal secretions or mast cell heparin.²¹⁰ Although we routinely utilize dextran sulfates as model compounds upon which HF activation can occur, other sulfated mucopolysaccharides may serve similar functions in vivo.^{211,212} The synovial fluid of patients with rheumatoid arthritis has been shown to contain plasma kallikrein, which has been shown to activate procollagenase to collagenase.²¹³ Uric acid and pyrophosphate crystals can act as surfaces for contact activation^{214,215} and may contribute to the inflammation of gout and pseudogout. A role for the contact activation system in inflammatory arthritis is therefore possible and may involve other functions of the enzymes formed in addition to any effects of kinins.

Activation of HF is also induced by the lipid A component of endotoxin,²¹⁶⁻²¹⁸ and contact activation proteins are depleted in endotoxic shock.²¹⁹⁻²²² The pooling of fluid into body cavities, the intravascular volume depletion, and the hypotension seen may be caused by release of bradykinin. Likewise, other bacterial infections such as typhoid fever have been shown to be associated with prekallikrein depletion, formation of kallikrein-C1 INH complexes, and C1 INH depletion as evidence of contact activation.²²³ In patients hospitalized because of trauma, the onset of sepsis has been shown to be associated with kininogen depletion, and determination of serial kininogen levels had prognostic value.²²⁰ An unfortunate circumstance has dramatized the kinin-forming capacity of HFf; trauma patients given plasma protein fractions (as plasma expanders) that were contaminated with HFf showed profound hypotension.^{224,225}

In patients with disseminated intravascular coagulation (DIC) due to endothelial injury and/or endotoxemia (including gram-negative sepsis, gram-positive sepsis, or viremia), decreased levels of plasma factor XII and prekallikrein, and kallikrein inhibitory activity are seen²²⁶; these changes were not observed in DIC associated with leukemia, carcinoma, or abortion.²²⁷ The data suggest activation of the HF-dependent pathways. A similar pattern of protein depletion has been observed in some patients with polycythemia vera,²²⁸ type II hyperlipidemia (familial hypercholesterolemia),²²⁹ and Rocky Mountain spotted fever.²³⁰ In some patients with nephrotic syndrome, a similar diminution of contact activa-

tion factors has been reported²³¹ that could not be explained simply by a loss of proteins in the urine.²³² Cirrhosis, as might be anticipated, is associated with diminished levels of plasma prekallikrein, HMW kininogen, and to a lesser degree, HF, which seems to be due to a diminished rate of protein synthesis.²³³

CONCLUDING COMMENTS

Considerable progress has been made in understanding the consequences of activation of the HF-dependent pathway of plasma. The various proteins and the functions of each have been characterized; yet we have little insight regarding the functions in normal homeostasis and are just beginning to appreciate the pathogenic roles in various inflammatory conditions and shock states.

The fact that patients deficient in HF, prekallikrein, or HMW kininogen do not bleed can be considered as evidence against the importance of contact activation in hemostasis. On the other hand, coagulation is one of the major consequences of HF activation and is the initiating stimulus every time a PTT is performed. Indeed, our concepts regarding bleeding per se are not well developed (particularly for spontaneous bleeding), and it is even conceivable that the absence of one or more contact activation factors (or plasma bradykinin) is protective against bleeding. Likewise, although factor XI deficiency is considered mild compared with factor VIII or IX deficiency, understanding why some patients do or do not bleed with very low levels of factor XI may provide an important piece of information. Areas in which bradykinin may be important in terms of normal physiology include control of the microcirculation in peripheral organs, particularly glandular tissue, and control of BP as a counterbalance to the renin-angiotensin system.

It appears likely that contact activation occurs in a variety of inflammatory conditions and may contribute to disease manifestations such as increased vascular permeability, angioedema, recruitment of polymorphonuclear leukocytes, and changes in BP. With new, more sensitive and specific assays for the components of contact activation, bradykinin, and their various inactivated and/or degradation products should come new insights regarding their roles in disease pathogenesis and new approaches to their inhibition.

A Human Monoclonal Autoantibody Recognizes a Neoantigen on Glycoprotein IIIA Expressed on Stored and Activated Platelets

By Diane J. Nugent, Thomas J. Kunicki, Cicely Berglund, and Irwin D. Bernstein

We prepared a heterohybrid cell line that secretes a human IgM monoclonal autoantibody that recognizes an antigen found on thrombin-activated or stored platelets. The surface expression of the epitope recognized by this autoantibody, 5E5, increases with time as platelets age in vitro, suggesting that it may represent a senescence or activation-specific antigen. 5E5 binds to the purified platelet membrane glycoprotein (GP) IIb-IIIa complex in an enzyme-linked immunosorbent assay (ELISA). In an immunoblot technique, 5E5 binds to a protein with an apparent mol wt of 95,000, which is identical to that of GPIIIa under

nonreduced conditions. In crossed immunoelectrophoresis (CIE), the predominant antigen recognized by 5E5 is contained in the GPIIb-IIIa precipitin arc. An additional precipitin arc recognized by 5E5 is often observed only on gels derived from lysates of platelets stored under blood bank conditions for >3 days. These findings illustrate the usefulness of human monoclonal antibodies for the identification of membrane neoantigens expressed as a result of platelet activation or revealed as platelets age in vitro.

CELLS OF hematopoietic origin have a well-defined lifespan in blood circulation that is unique for each lineage. Platelets, for example, circulate for 7 to 10 days before they are removed by the reticuloendothelial system, whereas the life span of RBCs in circulation is much longer at 120 days.¹⁻³ Selective removal of senescent hematopoietic cells suggests the existence of epitopes that are expressed on the cell surface only after aging. These antigens could be generated by various processes, such as proteolytic degradation, desialation, or activation. The presence in normal sera of naturally occurring autoantibodies that react with aged erythrocytes or platelets and the increased phagocytosis of aged cells by autologous monocytes following incubation in such sera have led some investigators to propose that immune-mediated clearance is an important mechanism in the removal of senescent cells.⁴⁻⁸

In studies of platelet surface antigens, murine monoclonal antibodies have proved invaluable for identification, characterization, and purification of specific membrane proteins or glycoproteins.^{9,10} These antibodies recognize interspecies differences, however, and they have not yet proved helpful for defining subtle membrane protein changes associated with aging that may be more likely to be recognized by human autoantibody. To characterize the specific membrane changes that lead to the expression of senescence antigens recognized by antiplatelet immunoglobulin in humans, methods to isolate large quantities of monospecific human autoantibody are necessary. Shoenfeld and co-workers¹¹

were among the first to isolate cell lines secreting human monoclonal antibody used to characterize the distribution of an autoantigen associated with systemic lupus erythematosus. Using a similar approach, we transformed B lymphocytes from a patient with immune-mediated thrombocytopenic purpura (ITP) using Epstein-Barr virus (EBV), and isolated B cell lines that secrete human monoclonal autoantibodies that bind to platelet antigens. We now report the characterization of one such human monoclonal autoantibody, 5E5, that recognizes a surface antigen expressed on platelets aged in vitro.

MATERIALS AND METHODS

Patient data. The bone marrow cells used in this study were obtained from a 1-year-old white female, after informed consent was obtained, as part of a routine diagnostic marrow aspiration to confirm the clinical impression of immune-mediated thrombocytopenic purpura (ITP). The patient had never been transfused with any blood product; EBV and cytomegalovirus (CMV) serologic studies were negative at both the initial visit and 6 weeks thereafter. The bone marrow showed increased numbers of megakaryocytes but was otherwise normal. Laboratory studies confirmed the presence of circulating platelet-reactive IgM, but no reactive IgG or IgA. The platelet count was consistently <5,000/mm³, thus preventing adequate evaluation of platelet-associated immunoglobulin.

EBV transformation. Bone marrow mononuclear cells were depleted of T cells using 2-aminoethylisothiuronium bromide (AET)-treated sheep RBCs (Sigma, St Louis). The remaining cells were infected with EBV by coinubation with the EBV-secreting cell line 1A2 (provided by M. Lostrom, Seattle) as previously described.¹² After 2 weeks, culture supernatants from wells containing transformed lymphocytes were screened for the presence of antiplatelet antibody using a solid-phase ¹²⁵I-protein A binding assay.¹³ Cells from positive wells were expanded and hybridized with a 6-thioguanine-resistant, mouse-human heterohybrid line, F6.¹⁴ The fused cells were placed in 96-well plates at 10⁵ cells/well and cultured in selective medium containing 15% fetal calf serum (FCS) in RPMI (GIBCO, Grand Island, NY), 0.01 mmol/L of hypoxanthine, 10⁻⁵ mol/L of aminopterin, 20 mmol/L of thymidine (HAT) to eliminate nonfused F6 cells, and 10⁻⁶ mol/L of ouabain to eliminate nonfused transformed lymphocytes. After 2 additional weeks, wells containing hybrid cells were screened for the presence of antiplatelet antibody, and cells from positive wells were cloned by the limiting dilution technique.

Antibodies. Two human monoclonal antibodies, 55 and 3H8, are used as isotype identical control antibodies in this study. Antibody 55 was isolated from peripheral blood lymphocytes from a

patient with malignant melanoma fused directly with F6 and is reactive with fibroblasts and melanoma cells but not platelets. Antibody 3H8 was used as a platelet-reactive positive control and was isolated from EBV-transformed splenic B lymphocytes from a 10-year-old patient with ITP. Both 55 and 3H8, like 5E5, are IgM molecules and bind staphylococcal protein A directly.

Indirect ^{125} I-Staphylococcal protein A platelet binding assay. To demonstrate binding of 5E5 to platelets aged in vitro, platelets were serially drawn from five individual donors at 96 hours, 48 hours, and 4 hours prior to incubation with the antibody preparation. In the interim between phlebotomy and antigen assays, platelet-rich plasma (PRP) fractions anticoagulated with acid citrate dextrose (ACD) (NIH Formula A) were stored sterilely in Fenwal PL-146 bags on an orbital platform rocker (70 cycles/min) at 22°C. In preparation for the platelet antibody binding assay,¹³ fresh or stored platelets were washed three times in Ringer's citrate dextrose (RCD), pH 6.8, and then pelleted by centrifugation. Two hundred microliters of the washed platelet suspension (2×10^5 platelets/ μ L) were incubated in RCD with 10 μ g of purified 5E5 or pooled human IgM (Cappel, Cochranville, PA) at 22°C for 60 minutes. Platelets were then washed twice in RCD, incubated with ^{125} I-staphylococcal protein A (10^5 cpm/sample) at 22°C for 30 minutes, washed twice again in RCD, and then counted in a γ counter (Packard Instruments, Downers Grove, IL).

Immunoblot of platelet proteins. Reactivity of human antiplatelet antibodies with platelet proteins was determined using the immunoblot technique described by Moroi and Burnette.^{15,16} In brief, 200 μ g of sodium dodecyl sulfate (SDS)-solubilized, ^{125} I-labeled protein, derived from 72-hour-old platelets outdated at the Puget Sound Blood Center, were electrophoresed under nonreducing conditions in an 8% polyacrylamide resolving gel using the discontinuous buffer system of Laemmli.¹⁷ The separated platelet proteins were then transferred to nitrocellulose paper using a Transblot apparatus (BioRad, Richmond, CA). After blocking with 1% gelatin (Sigma, St Louis) in 150 mmol/L of NaCl, individual strips of the nitrocellulose paper were incubated with each antiplatelet antibody or human serum for 60 minutes at ambient temperature, washed twice with 0.5% gelatin, 150 mmol/L of NaCl, 0.1% Triton X-100 (washing buffer), and then incubated with horseradish-peroxidase-linked goat anti-human IgM and IgG (Tago, Burlingame, CA). Immunoreactive protein recognized by enzyme-linked goat anti-human Ig was detected by developing the strips with the chromogen 4-chloro-1-naphthol dissolved in methanol, stock solution of 3 mg/mL. One volume of the stock solution was mixed with 5 vol 50 mmol/L of Tris-HCl, 200 mmol/L of NaCl, pH 7.4, and 0.015% H_2O_2 . Autoradiography of the strips was also performed to assure proper alignment of the platelet proteins.

Indirect immunofluorescence analysis of antibody binding to platelets. As described elsewhere by Andrews and colleagues,¹⁸ peripheral blood erythrocytes, mononuclear cells, granulocytes, and platelets were isolated and suspended in RCD to screen for surface binding of human monoclonal autoantibodies. Cells were incubated for 60 minutes at 22°C with either 5E5, 55, or pooled human IgM (10 μ g antibody/mL), washed twice in RCD, and incubated with fluoresceinated goat F(ab')₂-antihuman IgM (1:40 dilution) for 30 minutes at room temperature. The cells were washed twice with RCD and prepared for analysis by flow microfluorimetry (FACS 440 fluorescence-activated cell sorter, Becton Dickinson, Sunnyvale, CA).

Crossed immunoelectrophoresis. CIE was performed as previously described by Kunicki and co-workers.¹⁹ One hundred micrograms of lysate protein derived from fresh platelets or platelets stored under blood bank conditions for 72 hours at 22°C were electrophoresed at 10 V/cm for 60 minutes at 15°C in first-dimension gels consisting of 1% agarose and 0.5% (vol/vol) Triton

X-100 in 0.034 mol/L of Tris and 0.1 mol/L of glycine, pH 8.7 (Tris-Glycine). Electrophoresis in the second dimension was performed at 2 V/cm for 18 hours at 15°C. The second dimension consisted of a biphasic gel system with an intermediate gel containing 40 μ g/cm² ^{125} I-labeled human monoclonal antiplatelet antibody (either 5E5 or 3H8) and an upper gel containing the IgG fraction of polyclonal rabbit antiplatelet antisera (700 μ g/cm²). Gels were then washed, dried, and prepared for autoradiography as described.¹⁹

Platelet activation. Gel-filtered platelets were isolated from a PRP fraction of fresh whole blood collected in one-tenth volume ACD (formula A). The columns were prepared using sepharose 2B-CL (Pharmacia, Piscataway, NJ) equilibrated with modified Tyrode's buffer: 138 mmol/L of NaCl, 29 mmol/L of KCl, 0.42 mmol/L of $NaHPO_4$, 12 mmol/L of $NaHCO_3$, 0.5% bovine serum albumin (BSA), and 0.1% glucose, pH 7.4. Identical aliquots of these platelets were then exposed to either thrombin (final concentration of 0.5 U/mL) or Tyrode's buffer for 5 minutes under nonstirring conditions at ambient temperature. EDTA was not included in any of the buffers used in this experiment. Hirudin (final concentration of 4 U/mL) was added to both fractions followed by the addition of an equal volume of 2% paraformaldehyde (final concentration of 1% paraformaldehyde). After 30 minutes on ice, the fixed platelets were washed twice in RCD, and indirect immunofluorescence assays were performed as described above.

Platelet glycoprotein IIb-IIIa- or Ib-specific ELISA screening assay. Using a modification of the procedure described by Furihata and co-workers,²⁰ 1–5 μ g/mL purified platelet glycoprotein IIb-IIIa or Ib in carbonate buffer, pH 9.5, was applied to the surface of flat-bottom microtiter wells and incubated overnight at 4°C. Following two washes with PBS, 100 μ L of blocking buffer containing 1% gelatin, 135 mmol/L of NaCl, pH 7.4, was added to each well and incubated at room temperature for 30 minutes. The plates were washed twice with PBS, 0.05% Tween, pH 7.4 (PBS-Tween). Test monoclonal antibodies, pooled human IgM, or human plasmas at various dilutions were then applied in duplicate on each plate, and plates were incubated at room temperature for 60 minutes. Following two washes with PBS-Tween, a horseradish peroxidase-linked goat F(ab')₂ anti-human IgM and IgG was added at a dilution of 1:2000 in PBS-Tween and incubated for 30 minutes at room temperature. Bound antibody was detected using a 0.1 mol/L of sodium citrate buffer, pH 4.4, containing 0.015% H_2O_2 and 5 mg/10 mL of 2,2-Azinobi's (3-Ethylbenz-thiazoline sulfonic acid) (ABTS; Sigma) as the chromogenic agent.

RESULTS

Bone marrow lymphocytes obtained from a patient with ITP were cultured with EBV-secreting 1A2 cells. After 2 weeks in culture, 384 wells (76.8%) contained EBV-transformed lymphocytes. Using an indirect ^{125} I-staphylococcus Protein A binding assay, supernatant fluids in 16 (4%) of the 384 wells were shown to contain antiplatelet antibody. One of the antiplatelet antibodies, 5E5, which was of the IgM isotype, was selected for further characterization, hybridized with F6, and cloned using limiting dilution techniques. This line grows stably in culture and secretes 20 to 30 μ g/mL of antibody when cultured overnight at a cell density of 5.0×10^5 /mL.

Using an indirect immunofluorescence assay and flow microfluorimetry, the surface reactivity of 5E5 with whole blood elements was compared with a non-platelet-binding negative control human antibody 55 and to pooled human IgM. 5E5 did not bind to normal peripheral blood mononu-

clear cells, granulocytes, or erythrocytes, but did bind strongly to the surface of ~70% of the platelets (Fig 1). This pattern of reactivity was consistently observed whether single donor or pooled platelet preparations were used.

As outdated platelets (>72 hours old, Puget Sound Blood Center, WA) were initially used for screening in both the radioimmunoassay and microfluorimetry experiments, studies were performed to test the possibility that there may be a progressive increase in the expression of this antigen during in vitro aging and/or platelet activation. Using the ^{125}I staphylococcal Protein A binding assay, surface reactivity of 5E5 with platelets derived from five individuals was measured during the course of storage of these cells in vitro. The results of this experiment are illustrated in Fig 2 and represent mean values $\pm$ SD for five separate experiments. We observed negligible binding of 5E5 to fresh resting platelets as compared with an isotype identical negative control, 55, or pooled human IgM. With in vitro storage, however, there was a four- to five-fold increase in expression of the platelet antigen recognized by 5E5 at 48 and 96 hours, whereas there was still minimal binding of the two negative control antibodies to these aged platelets. Furthermore, by indirect immunofluorescence assays, fresh thrombin-stimulated platelets expressed the epitope recognized by 5E5 (Fig 3); again, ~60% to 70% of platelets were positive for this antigen in the activated platelet population.

Reactivity of 5E5 for GPIIb-IIIa was demonstrated in an ELISA system using plates coated with purified platelet GPIIb-IIIa or GPIb, as shown in Fig 4. In this study, 5E5 reacted specifically with GPIIb-IIIa but not with GPIb, whereas pooled human IgM and six other platelet reactive human monoclonal autoantibodies at similar IgM concentrations did not show binding to either of these adsorbed glycoproteins. Using human plasmas containing alloantibodies known to react with either GPIIb-IIIa (anti-PI^{A1}) or GPIb (anti-PI^{E1}), we were able to confirm the antigen specificity of this assay.

An immunoblot technique was used to identify any platelet proteins recognized by 5E5 (Fig 5). Protein derived from

Fig 1. Indirect immunofluorescence analysis of antibody binding to stored platelets using flow microfluorimetry. The reactivity of 5E5 was compared with a nonplatelet binding negative control autoantibody, 55, and pooled human IgM. The autoantibody 5E5 binds to an epitope present on only 70% of the platelet population.

Fig 2. Indirect ^{125}I -staphylococcal Protein A platelet binding assay demonstrating reactivity of 5E5 as platelets age in vitro. The increase in expression of the epitope recognized by 5E5 is progressive as platelets age or become activated with storage, as compared with pooled human IgM or an isotype identical negative control human IgM monoclonal antibody. The results are mean values $\pm$ SD for five separate experiments.

Fig 3. Indirect immunofluorescence analysis of antibody 5E5 binding to fresh resting v thrombin-activated platelets. As observed in stored platelets, a subset of thrombin-activated, fresh platelets (60%) demonstrates increased expression of the epitope recognized by 5E5 when compared with human IgM, the negative control antibody.

Fig 4. Enzyme-linked immunosorbent assay (ELISA) using purified GPIIb-IIIa adsorbed onto microtiter plates. Human plasmas specific for PIA¹ (○), control plasmas from normal individuals, pooled human IgM in tissue culture supernatant, six other platelet-reactive human monoclonal autoantibodies at similar concentration (●), and 5E5 supernatant (△) were tested on GPIIb-IIIa in triplicate. Only the 5E5 supernatants and human plasma with known anti-PIA¹ reactivity bound to the GPIIb-IIIa-coated plates. There was no reactivity of 5E5 or the PIA¹ positive plasmas on GPIb-coated plates (not shown).

whole platelet lysates was first separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and then transferred to nitrocellulose paper. 5E5 bound to a protein with an apparent mol wt of 95,000 under nonreduced conditions using lysates from either fresh or stored platelets, whereas other isotype-identical human monoclonal antibodies, at similar concentrations, did not bind to this protein in the identical lysate preparation (Fig 5). Plasma samples containing anti-PIA¹ antibodies known to react with GPIIIa were run simultaneously on the same immunoblot and bound to a platelet protein that comigrated with the protein recognized by 5E5.

In CIE studies, 5E5 reacted with the GPIIb-IIIa precipitin arc from both fresh and aged platelet preparations (Fig 6A). The control antibody, 3H8, did not bind to any of these precipitin arcs in lysates of either fresh or aged platelets (Fig 6B). In certain studies, 5E5 also bound strongly to a precipitin arc containing an as yet unidentified antigen that is often but not always present in lysates derived from stored platelets (Fig 6A). This precipitin arc was never observed in lysates prepared from fresh platelets.

DISCUSSION

We described the identification and preliminary characterization of a platelet antigen recognized by a human monoclonal autoantibody, 5E5, isolated from an ITP patient who, prior to this study, had never received any blood product. One explanation for the increased expression of the

Fig 5. Immunoblot of platelet proteins. Under nonreducing conditions, 5E5 bound to a protein of 95,000 mol wt, as seen in lane 4. A nonplatelet binding human IgM monoclonal antibody isolated from an Epstein-Barr virus (EBV)-transformed cell line was also incubated with nitrocellulose strips as a negative control (lane 6). Antibody 3H8, a platelet-reactive human monoclonal autoantibody used in the crossed electroimmunophoresis studies, is shown in lane 5. Simultaneously, a normal plasma in lane 2 and a plasma containing anti-PIA¹ antibodies in lane 3 were screened for reactivity with immunoblotted platelet proteins. As is apparent in lane 3, the anti-PIA¹ antibodies reacted with a protein that comigrates with the protein recognized by 5E5.

5E5 epitope on GPIIIa is that platelets aged *in vitro* become activated during storage, resulting in specific membrane changes and the appearance of otherwise cryptic antigens on the cell surface. Rearrangements in the platelet membrane associated with activation, adhesion, or secretion are known to reveal neoantigens that might trigger immune-mediated clearance of these cells from the circulation.²¹⁻³² Increased levels of cell associated Ig resulting in shortened cell survival has been described for aged erythrocytes, monocytes, and platelets, as well as in disease states in which there is increased intravascular platelet activation.^{4-6,33,34,39} Therefore, it is reasonable to hypothesize that the expression of neoantigens as a result of senescence or activation leads to the binding of naturally occurring autoantibodies, accelerating clearance from the circulation.

In this study, we used platelet storage conditions that would currently be considered suboptimal, ie, storage in PL-146 containers on a rotary platform shaking apparatus.

Fig 6. Crossed immunoelectrophoresis of platelet proteins. (A) The antibody 5E5 reacted with the GPIIb-IIIa precipitin arc from both fresh and aged platelet preparations. 5E5 also bound to an as-yet-unidentified precipitin arc present only in lysates prepared from stored platelets. (B) The control human antiplatelet antibody, 3H8, did not bind to any of these precipitin arcs in lysates of either fresh or aged platelets.

This decision reflects our intention to reproduce conditions that have been previously reported³⁵⁻³⁸ to result in altered platelet function and, perhaps, changes in platelet glycoprotein composition. In so doing, we hoped to mimic in vitro the effects of platelet aging in vivo. Use of optimal storage conditions, eg, PL-732 containers, and proper shaking apparatuses, would probably not result in significant platelet activation or glycoprotein changes. To demonstrate that this is so was not the thrust of the present study, however.

Isolation of senescence determinants from hematopoietic cells has thus far focused on erythrocyte antigens. Using antibody eluted from 50 L of aged erythrocytes, Kay³³ was able to immunoprecipitate a protein with an apparent mol wt of 62,000 that was believed to be related to band 3 of aged human erythrocytes. Using monospecific antibodies produced by rabbits immunized with this purified protein, Kay³⁴ identified polypeptides immunologically related to erythrocyte band 3 not only on other hematopoietic cell lines, such as mononuclear leukocytes and neutrophils, but also on nucleated somatic cells, such as human fibroblasts and squamous epithelium.

The unstimulated platelet undergoes an immediate shape change when exposed to specific agonists such as thrombin or ADP, resulting in the propagation of pseudopods and expression of receptors for circulating coagulation factors.^{22,23} Alterations in the association of GPIIb-IIIa with the platelet

cytoskeleton have also been reported following activation,²³⁻²⁶ and thrombin-induced secretion results in the expression of fibronectin, α granule membrane protein, and thrombospondin on the platelet surface.²⁷⁻³¹ In disease states associated with increased platelet destruction, increased quantities of plasma glycocalicin, a soluble glycopeptide derived from GPIb by the calcium-activated protease, calpain, have been demonstrated.³²

Similarly, aging or activation of platelets during storage under blood bank conditions results in both quantitative and qualitative changes in membrane glycoproteins. George³⁵ was among the first to report a decrease of $51\% \pm 4\%$ in membrane GPI in platelets which had been stored for 72 hours. These results were extended by the observations of White and colleagues,³⁶ who found a decrease in all major glycoproteins within 48 hours of storage. Furthermore, similar to our findings with in vitro aging, White described the appearance of several new polypeptides in stored platelets with electrophoretic mobilities corresponding to 260,000, 240,000, and 84,000. Bolin and colleagues³⁷ suggested that two additional glycoproteins, GP44 and GP77, which increase in expression as platelets age in vitro, may be proteolytic products of the GPIb molecule itself, since the appearance of these molecules on the platelet surface correlates statistically with a decrease in membrane GPIb. Alterations in platelet membrane glycoprotein composition may

account for the decreased adherence of stored platelets to subendothelium as determined by the Baumgartner perfusion technique.³⁸ These examples of membrane glycoprotein changes that occur during aging, activation, or damage represent just a few of the possible mechanisms for expression of new antigens that could target the platelet removal from the circulation.

The identification of platelet senescence or activation antigens using human autoantibodies reactive with these membrane proteins thus establishes a framework for further definition of the cellular and biochemical mechanisms

involved in the clearance of aged or damaged platelets in normal terminal maturation. Further studies are in progress to identify more precisely the nature and location of the epitope recognized by 5E5 on the GPIIIa molecule as well as to determine those conditions associated with increased expansion of the 5E5 epitope on platelets. The use of human monoclonal autoantibody from EBV-transformed B cell lines, rather than serum antibodies, provides a means to examine the expression of platelet antigens relevant not only to normal senescence of these cells but also to disease states characterized by increased platelet clearance.

An Evaluation of Crossmatching, HLA, and ABO Matching for Platelet Transfusions to Refractory Patients

By Joanna M. Heal, Neil Blumberg, and Debra Masel

Refractoriness occurs in many patients receiving multiple platelet transfusions. We used a sensitive ELISA assay to assess the utility of crossmatching HLA-A,B matched single donor platelets in 51 consecutive, typical refractory patients. Of the 222 transfusions evaluated at 1 to 4 hours posttransfusion, only 17 of 54 (31%) with positive crossmatches had corrected platelet count increments of $\geq 7,500/\mu\text{L}$. In contrast, 95 of 168 (57%) of those with negative crossmatches had such increments ($P < .001$). Regardless of the results of the crossmatch, HLA-A,B, and ABO matching had independent influences on transfusion outcome. The median corrected 1- to 4-hour increment for crossmatch negative transfusions was 13,300/ μL for A/BU grade matches, 9,700 for BX, and 7,800 for C. Increments were 10,000/ μL for ABO-identical transfusions and 5,900 for transfusions of platelets ABO incompatible with the recipient's plasma antibodies. When the donor platelets were ABO compatible, but the donor plasma contained

ABO antibodies to the recipient's platelets, the increment was intermediate (8,200/ μL). The most important factor in predicting platelet survival was the crossmatch, followed by HLA-A,B and ABO, each having independent predictive value. These data demonstrate that the predictive value of a negative crossmatch may be considerably less than that reported in previous studies with stable, less ill patients. In typical refractory patients, there appear to be mechanisms of platelet destruction that are related to HLA-A,B and ABO but are not detected with current crossmatch methods. We hypothesize that soluble plasma HLA-A,B and ABO antigens contribute to the destruction of donor and sometimes recipient platelets by an immune complex or other "innocent bystander" mechanism. With our crossmatching technique, HLA-A,B and ABO match grades remain relevant to platelet transfusion therapy in some refractory patients.

SINCE THE 1960s, platelet transfusion therapy has become vital to the prophylaxis and therapy of bleeding disorders in patients with leukemia, aplastic anemia, some lymphomas, and solid tumors.¹ The availability of effective platelet transfusion products has decreased mortality from bleeding in these patients.² Perhaps 50% of multiply transfused patients become clinically refractory.^{3,4} The causes of refractoriness to platelet transfusion appear to be primarily immunological,⁵ although factors other than alloimmunization may play an important role.⁶ HLA-A,B matching is one approach that has been fruitful in dealing with some refractory patients.⁷

Recently, questions have been raised as to whether refractoriness to platelet transfusion occurs purely on the basis of immunologic mechanisms.⁸ Such doubts are reasonable because the patients in question often have fever, infection, bleeding, coagulopathy, and splenomegaly. These nonimmunologic factors are known to decrease platelet recovery and survival. Sensitive and specific crossmatch techniques are now available for detection of IgG and IgM binding to donor platelets.⁹⁻¹¹ These tests appear to predict posttransfusion survival of platelets in patients with alloantibodies to donor platelets. However, many published studies excluded patients with the previously mentioned common factors that contribute to increased platelet consumption. Therefore, only a very small subset of refractory patients has been examined in detail.

We developed a sensitive enzyme-linked antiglobulin assay, and used it to evaluate platelet crossmatching retrospectively in typical refractory patients. We did not exclude any patients, because the utility of crossmatching in refractory patients preselected on the basis of alloimmunization has been clearly demonstrated.⁹ We reasoned that a study that does not exclude any patients would yield a realistic assessment of the potential benefits of crossmatching in typical clinical practice. It might also provide useful insights into the refractory state that could be missed if the study

were limited to patients who were alloimmunized as defined by lymphocytotoxic antibodies.

In addition, we analyzed the role of HLA-A,B and ABO matching because no analysis encompassing all these potentially important immunologic factors has been reported.

METHODS

Patient selection. Single donor platelets collected from a closely HLA-A,B matched, unrelated individual were crossmatched retrospectively against recipient plasma in 51 consecutive refractory patients for 316 transfusions. All patients had received RBC products from which leukocytes had not been removed, as well as numerous random donor platelet transfusions. All patients had had at least two previous transfusions of pooled random donor platelet concentrates that failed to yield satisfactory corrected platelet count increments ($\geq 7,500/\mu\text{L}$ at 1 to 4 hours). Lymphocytotoxicity screening for anti-HLA-A,B antibodies was not routinely performed, but all patients had detectable antiplatelet antibody by our enzyme-linked immunosorbent assay (ELISA) technique. patient received granulocyte transfusions, concomitant with the platelet transfusions being evaluated by our crossmatch technique.

None of these patients was free of the "nonimmunologic factors" known to shorten platelet survival. That is, all had one or more of the following factors: fever $>99^{\circ}\text{F}$, sepsis or systemic infection, splenomegaly, consumption coagulopathy, bleeding, or a previous history of autoimmune thrombocytopenia. Determination of these factors was made by the physicians caring for the patient and was documented in the medical record. The presence or absence of these factors was not determined for each individual platelet transfusion.

The primary diagnoses were acute nonlymphocytic leukemia (21), solid tumor (5), acute lymphocytic leukemia (4), chronic myelogenous leukemia (3), preleukemia (3), aplastic anemia (2), lymphoma (2), and other hematological conditions such as myelofibrosis, erythroleukemia, multiple myeloma, etc. (11). Three of the patients were children aged <5 years. The other patients were adults. Three patients had undergone autologous or allogeneic bone marrow transplantation.

The HLA-A,B match grades of the platelet transfusions were A (7), BU (37), BX (71), and C (201). The data on the A and BU transfusions were pooled for analysis. Of the 51 patients, 25 received three or more evaluable transfusions. Of these, 16 received both B and C matches. Posttransfusion platelet count increments were measured in all patients, and the counts were corrected for body surface area and number of platelets transfused.⁹ Not all patients had increments measured at both 1 to 4 and 18 to 24 hours as planned; 222 transfusions had posttransfusion platelet counts done at 1 to 4 hours. The other 94 had the initial count done between 5 and 24 hours posttransfusion; 107 transfusions had counts performed at two posttransfusion time points.

Crossmatch technique. Immulon II microtiter plates (Dynatech, Chantilly, VA) are washed three times using distilled water. A murine monoclonal antibody that reacts with an undefined antigen present on all human platelets (UR 1-6.6 produced by the Laboratory Medicine Division Hybridoma Facility) is added to each well in the amount of 100 μL at a concentration of $\sim 10 \mu\text{g}/\text{mL}$ in coating buffer (1.59 g/L Na_2CO_3 , 2.93 g/L NaHCO_3 , pH 9.6). The plate is then incubated for 2 hours at 37°C and then overnight at 4°C . The antibody is used as crude mouse ascitic fluid. Platelets are first sedimented and resuspended in phosphate-buffered saline (PBS)-EDTA (0.01 mol/L of $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, 0.15 NaCl, 3 g/L Na_2EDTA , pH 7.0) prior to adhering to the plate. After resuspension in PBS-EDTA at a count of 370,000/ μL , a 100- μL aliquot of platelets is added to each of two wells for each plasma to be tested. After platelets are added, the microtiter plate is centrifuged at 1,800 rpm in a GLC-4 centrifuge for 10 minutes to sediment the platelets onto the monoclonal antibody-coated surface. The plate is then incubated at room temperature for 50 minutes and is then washed semiautomatically, without need for centrifugation, three times using PBS (pH 7.2) and a Dynatech Mini-Wash. PBS-1% bovine serum albumin (BSA; BCA, West Chester, PA) 100 μL is added to each well to reduce nonspecific adsorption of plasma proteins and enzyme-antiglobulin conjugate during subsequent steps. This step requires a 30-minute room temperature incubation, and is followed by two further washes with PBS-1% BSA.

Test plasmas are diluted 1:2 in PBS-1% BSA to reduce nonspecific binding. Each diluted plasma (100 μL of each) is added to each of two wells and incubated for 45 minutes at 37°C if IgG is to be measured, or for 60 minutes at room temperature if IgM is to be measured. Appropriate positive (anti- PI^{A}) and negative plasma controls are also run in duplicate. The plate is washed three times using PBS-1% BSA, and 100 μL of alkaline phosphatase linked to affinity-purified anti-human IgG or IgM (Sigma Chemical, St Louis) is then added at a dilution previously optimized to the lot in question. The conjugates are usually used at 1:800 or 1:1,000

dilutions. Two wells receive no conjugate to serve as negative controls for nonspecific binding by the anti-IgG-enzyme conjugate. A further incubation at 37°C for 45 minutes (IgG) or room temperature for 60 minutes (IgM) is performed, followed by three PBS-1% BSA washes. Substrate, 1 mg/mL of *para*-nitrophenyl phosphate (Sigma) in 0.05 mol/L of Na_2CO_3 , 0.001 mol/L of MgCl_2 , pH 9.8 is added at 100 $\mu\text{L}/\text{well}$. Color development is measured spectrophotometrically¹² with a Dynatech MR600 microtiter plate reader coupled to an Apple IIe microcomputer for which kinetic-ELISA (k-ELISA) programs have been written by Dr Jonathan Cowles, Pittsford, NY; $\Delta\text{A}405 \text{ nm}/\text{min} \times 1,000$ is computed by least-squares linear regression of absorbance readings taken at 20, 25, 30, and 35 minutes after substrate addition. The correlation coefficient for the linearity of the $\Delta\text{A}405 \text{ nm}$ v time is usually 0.99, thus confirming the measurement of first-order enzyme kinetics, which we previously showed to correlate linearly with the amount of IgG and anti-IgG bound. The assay is linear throughout the range used.¹² The amount of IgG bound to the solid-phase platelet layer is reported as the mean of the duplicate determinations of $\Delta\text{A}405 \text{ nm}/\text{min} \times 1,000$. The duplicate values are usually within 10% to 20%. Because the kinetic measurement of enzyme activity is made at ambient temperature, controls are run to normalize the results from day to day.

The binding to platelets of IgG from plasmas of nonthrombocytopenic hospitalized patients yields a normal range of 0 to 1.08 for $\Delta\text{A}405 \text{ nm}/\text{min} \times 1,000$ (mean $\pm 2 \text{ SD}$, $n = 225$). The range for binding of IgM is 0 to 9.69 (mean $\pm \text{SD}$, $n = 122$). The positive control for the IgG assay is an anti- PI^{A} whose $\Delta\text{A}405 \text{ nm}/\text{min} \times 1,000$ is usually ~ 8.00 to 10.0 when run at a 1:1,000 dilution. The positive control for the IgM assay is a plasma from a patient with leukemia and autoimmune thrombocytopenia, which usually gives a $\Delta\text{A}405 \text{ nm}/\text{min} \times 1,000$ of 15 to 20 when tested at a dilution of 1:4. This latter plasma reacted with every donor platelet we tested. A positive crossmatch in both IgG and IgM assays was defined as binding $>2 \text{ SD}$ above the control means described above.

Titers of four randomly selected anti-HLA-A,B antibodies were 1 to 2 orders of magnitude higher with this k-ELISA technique than by lymphocytotoxicity assays. Titers of two anti- PI^{A} antibodies were 1 to 3 orders of magnitude greater by k-ELISA than by complement fixation techniques or ^{51}Cr release platelet cytotoxicity methods. Thus, we believe that the technique is probably of similar sensitivity to radioimmune⁹ or immunofluorescent¹¹ methods previously shown to be useful as platelet crossmatches. Although anti-A and -B blood group antibodies are detected by this assay, many patients nonetheless exhibit negative crossmatch results with ABO-incompatible platelets.

All patient plasmas were routinely tested (crossmatched) against four to six randomly selected normal donor platelets at the same time that the crossmatch was performed with the HLA-A,B matched platelets that were transfused. All patients had at least one positive crossmatch during the course of these tests, with almost all showing incompatibility with several non-HLA-A,B matched platelets. All HLA-A,B matched platelets for transfusion were also crossmatched with two to four normal plasmas. This approach allowed us to detect donor platelets that might have significantly elevated levels of IgG or IgM. Such platelets yield positive crossmatches even with normal donor plasmas. Donor platelets with elevated platelet-associated IgG (PAIgG) or IgM occurred very rarely and were excluded from the data reported.

Platelets were stored no more than 1 to 5 days at 4°C prior to crossmatching. Such storage does not alter the level of platelet surface IgG or IgM, or the binding of plasma IgG or IgM during a crossmatch (data not shown).

Measurement of PAIgG. PAIgG assay is a technical variant of that described for the detection of plasma anti-platelet antibody.¹³

PAIgG or soluble IgG standards compete with solid-phase IgG for binding to an alkaline phosphatase-linked anti-IgG antiglobulin reagent. The principle of the assay is that increased concentrations of soluble IgG or PAIgG will compete for anti-IgG and reduce anti-IgG binding to the solid-phase IgG. This assay can reproducibly detect changes of ~50 molecules per platelet of IgG.

Definitions of HLA and ABO match grades. For HLA, A matches are identical at all four HLA-A,B loci; BU matches are those sharing only two or three HLA-A,B antigens present on recipient cells yet possessing no HLA-A,B antigens that differ from those of the recipient due to being homozygous at one or both HLA-A,B loci; BX matches are those with one donor HLA-A,B antigen differing but cross-reactive with one of those of the recipient; C matches are those in which there is one non-cross-reactive antigen present on the donor cells that differs from those of the recipient. BUX matches were classified as BX.

For ABO, identical transfusions are those in which both donor and recipient are of the same ABO type (eg, an A donor to an A recipient); ABO "plasma-incompatible" transfusions are those in which the platelets do not carry antigens incompatible with recipient plasma, but in which the donor plasma contains antibody to ABO antigens possessed by the recipient (eg, an O to an A); in ABO "platelets-incompatible" transfusions, the donor platelets carry ABO antigens to which the recipient has antibody (eg, an A to an O).

Statistical analysis. All analyses were made using an Apple Macintosh microcomputer (Cupertino, CA) and NCSS software (Dr Jerry L. Hintze, Utah State University, Kaysville). Comparisons of medians of multiple groups were performed using nonparametric multivariate methods (Kruskal-Wallis). Medians were reported throughout the analysis because the data were not all normally distributed. The results of the analyses using parametric analyses that assume normally distributed data were identical to those reported. When statistically significant findings existed, individual comparisons of groups were made using the Mann-Whitney two-sample test, which is the nonparametric equivalent of the unpaired *t* test. Comparison of frequencies of events was performed using chi-square contingency tables, with individual frequencies being further compared to each other with Fisher's exact test. In addition, a three-way analysis of variance (ANOVA) was performed to assess the independent contributions of crossmatch results, HLA-A,B and ABO match grades to platelet count increments, and any interactions between these variables.

RESULTS

Of the 316 IgG crossmatches performed, 88 (28%) were positive. The frequency of positive crossmatches did not vary significantly with HLA match grade: A (14%), BU (28%), BX (28%), and C (30%). This conclusion applies only to BU, BX, and C matches because only seven A matches were studied.

The IgG crossmatch positivity rate was 33 of 129 for ABO identical transfusions (26%), 26 of 90 for ABO plasma-incompatible transfusions (29%), and 31 of 97 for donor ABO platelets-incompatible transfusions (32%). However, A donor platelets crossmatched with O recipients had the highest crossmatch positivity rate—23 of 54 (43%; $P < .02$ v ABO identical and $P < .07$ v ABO plasma-incompatible transfusions).

The IgM crossmatch positivity rate did not vary with HLA or ABO match grade. Of 308 IgM crossmatches performed, 41 (13%) were positive. However, in only 15

instances were the IgM crossmatches positive and the IgG negative. There was no clear correlation between posttransfusion corrected increment and crossmatch results in these few discrepant cases.

The success rate at 1 to 4 hours posttransfusion (a corrected platelet count increment $\geq 7,500/\mu\text{L}$) was 95 of 168 for crossmatch-negative transfusions (57%) and 18 of 54 for crossmatch-positive transfusions (33%) ($P < .001$). The success rate varied significantly with HLA and ABO match grade even for crossmatch-negative transfusions: A/BU (74%); BX (62%); C (51%)—ABO identical (66%); ABO plasma incompatible (54%); ABO platelets incompatible (43%). These differences were significant for A/BU v C ($P = 0.03$), and for ABO identical v ABO platelets incompatible ($P = 0.01$).

The median corrected platelet count increments arranged according to HLA match grade for crossmatch-negative transfusions are shown in Fig 1. A similar trend was observed for crossmatch-positive transfusions, but this was not statistically significant. Corresponding data arranged according to the degree of ABO match are shown for crossmatch-negative (Fig 2) and crossmatch-positive (Fig 3) transfusions. Regardless of the crossmatch results, ABO identical platelets gave significantly better results.

The role of HLA match grade was particularly notable when time periods ≥ 5 hours posttransfusion were examined (Fig 4). At these later time points, crossmatch-negative C match transfusions yielded increments in platelet count that were significantly inferior to those of A/BU and BX matches. The degree of ABO compatibility did not correlate significantly with posttransfusion increments at ≥ 5 hours posttransfusion, although a trend toward better results with ABO-identical platelets was observed.

To assess the relative roles of crossmatching, HLA matching, and ABO matching in predicting platelet count increments, two- and three-way ANOVAS were performed to assess the independent and interactional contributions of these factors. Crossmatching was the most significant predictive factor for corrected platelet count increments performed 1 to 4 hours posttransfusion ($P = .002$ v HLA-A,B and ABO). HLA matching ($P = .02$ v ABO) and ABO

Fig 1. Crossmatch negative transfusions. Median corrected 1- to 4-hour posttransfusion platelet count increment plotted according to the HLA-A,B grade of the match. $P < .001$ for the three groups by Kruskal-Wallis. $P < .05$ for A/BU v C, $P = .16$ for A/BU v BX, and $P = .10$ for BX v C by Mann-Whitney.

Fig 2. Crossmatch negative transfusions. Median corrected 1- to 4-hour posttransfusion platelet count increment plotted according to the ABO relationship between donor and recipient. The Kruskal-Wallis analysis yielded a significant difference among the groups ($P < .05$). $P = .07$ for platelets ABO identical v platelets ABO incompatible by Mann-Whitney. When grouped according to HLA-A,B match grade, the difference between platelets ABO identical and platelets ABO incompatible yielded $P = .12$ for C matches, $P = .03$ for BX matches, and $P = .15$ for A/BU matches. The differences between plasma ABO incompatible and the other two groups were not statistically significant ($P = .16$ v identical; $P = .83$ v platelets incompatible). When the two groups of ABO nonidentical platelets were merged and compared with the ABO-identical platelets group, the difference was significant ($P = .048$).

matching ($P = .08$ v crossmatching) had independent effects to a lesser degree. None of the interaction terms in these analyses was significant, confirming the largely independent roles of these three factors.

When the transfusions are grouped by crossmatch results, HLA-A,B match grade and ABO match grade, and then ranked by median corrected platelet count increment performed 1 to 4 hours posttransfusion, the independent and significant roles of these factors are clear (Table 1). Favor-

Fig 3. Crossmatch positive transfusions. Median corrected 1- to 4-hour posttransfusion platelet count increment plotted according to the ABO relationship between donor and recipient. The Kruskal-Wallis analysis did not yield a significant difference among the groups ($P = .19$). When the two groups of ABO nonidentical platelets were merged and compared with the ABO-identical platelets group, the difference in the medians by Mann-Whitney test was significant at $P = .07$.

Fig 4. Crossmatch negative transfusions. The median corrected posttransfusion platelet count increment at times ≥ 5 hours posttransfusion according to HLA-A,B match grade. BU includes A matches as well. By Kruskal-Wallis, the differences between A/BU and BX were not significant at any point, and the differences between C matches and both A/BU and BX matches were significant at all time points ($P < .05$ by Kruskal-Wallis for 5 to 12 and 13 to 18 hours; $P < .05$ by Mann-Whitney for BX v C at ≥ 19 hours posttransfusion).

able HLA and ABO match grades can apparently compensate for crossmatch incompatibility in some instances. For example, the small number of crossmatch-positive A, BU and BX transfusions that were also ABO identical did as well or better than crossmatch-negative C matches that were ABO platelets incompatible. Similarly, ABO matching can compensate for poorer HLA-A,B matching. Crossmatch-negative C matches that were ABO identical did as well or better than crossmatch-negative BX matches that were ABO nonidentical.

An unexpected finding was that after crossmatch-positive transfusions, the platelet count at 1 to 4 hours posttransfusion was frequently lower than the pretransfusion platelet count. Fifteen of 54 crossmatch-positive transfusions (27%) led to platelet count decrements as compared with only 14 of 168 (8%) for crossmatch-negative transfusions ($P < .0005$). A separate analysis of this phenomenon will be reported elsewhere.

To assess whether the decreased survival of transfused platelets in patients receiving crossmatch-negative transfusions might have an immunological basis, we measured PAIgG in 18 of our refractory patients at various times during the period when transfusions were given. All the refractory patients, including those receiving predominately crossmatch-negative platelets, had elevated PAIgG at the levels seen in autoimmune thrombocytopenia (Fig 5). However, none of these patients had received exclusively crossmatch-negative, HLA-A,B-identical, and ABO-identical platelet transfusions. Elevations of PAIgG were noted after transfusions of both crossmatch-positive and crossmatch-negative platelets, as well as prior to transfusion with HLA-A,B-matched platelets.

DISCUSSION

Our study represents the first attempt to evaluate in one group of patients the three known immunologic factors that affect the success of platelet transfusions to refractory patients—crossmatching, HLA-A,B matching, and ABO

Table 1. Corrected Platelet CI According to Crossmatch Results, HLA-A,B and ABO Match Grades: Ranked by Median Corrected Increment

CI	X-M	HLA*	ABO	n	Success Rate (% CI $\geq 7,500/\mu\text{L}$)
17,700	Neg	BU	Platelets incompatible	7	86
17,000	Neg	BU	Plasma incompatible	7	71
11,400	Neg	BX	Identical	22	73
11,300	Neg	BU	Identical	9	67
11,100	Pos	BU/BX*	Identical	9	56
10,400	Neg	BX	Plasma incompatible	11	82
9,300	Neg	C	Identical	43	63
5,100	Neg	BX	Platelets incompatible	9	11
5,100	Pos	C	Identical	10	40
4,500	Neg	C	Platelets incompatible	26	42
4,300	Neg	C	Plasma incompatible	34	41
3,300	Pos	BU/BX	Plasma incompatible	2	0
1,000	Pos	C	Platelets incompatible	14	29
900	Pos	C	Plasma incompatible	13	23
200	Pos	BU/BX	Platelets incompatible	6	17

NOTE. The median category is an increment of 5,100/ μL . Of the crossmatch negative groups, seven fell at or above the median, only two fell below. Of the BU or BX match groups, seven fell at or above the median category, only two fell below. Of the five ABO-identical groups, all five fell at or above the median, none fell below. Conversely, most of the crossmatch-positive or C-match or ABO-platelet incompatible groups fell below the median group.

Abbreviation: CI, count increment.

*Only four A matches were included in these data and are grouped with the BU matches. Because so few BU and BX matches were crossmatch positive, these data were pooled for positive crossmatches.

matching. On initial examination, our results showing relatively poor predictive performance of a sensitive crossmatch may appear to conflict with optimistic prior reports.^{9,11,14-17} However, in some previous crossmatching studies patients were selected to be free of sepsis, severe bleeding, consumption coagulopathy, and splenomegaly.¹⁴⁻¹⁷ In our study and others,^{8,18-21} all patients were included. Our results are very similar to those reported in studies in which no patients were excluded (Table 2). All studies found positive predictive values (percentage of failures after a positive crossmatch) that were in the range of 70% to 100%. However, the negative predictive value (percentage of successes when the crossmatch was negative) was consistently higher (80% to 92%) in studies with preselected patients,¹⁴⁻¹⁷ and consistently lower (52% to 77%) when all patients were included.^{8,18-21} These lower success rates in typical refractory patients occurred regardless of crossmatch methodology used, including sensitive techniques such as radioimmunoassay.

"Nonimmunologic" factors such as infection, consumption coagulopathy, fever, bleeding, and splenomegaly may have accounted for the fact that 43% of our crossmatch negative transfusions yielded unsatisfactory increments. Inconsistent with this interpretation is the observation that the 45 crossmatch-negative transfusions of BU or BX match grade yielded a failure rate of only 26% (top four lines in Table 1). This failure rate of crossmatch-negative, closely HLA-A,B matched transfusions compares well with the

Fig 5. The platelet-associated IgG (PAIgG) in 18 refractory patients, measured by a competitive enzyme-linked immunosorbent assay (ELISA) technique is shown. The amounts are in femtograms (fg) of soluble IgG equivalents per platelet.¹³ None of the patients had normal values, including those who had received predominately crossmatch negative transfusions. These levels were generally measured at the nadir of the patient's platelet count, although all patients had received multiple RBC and platelet transfusions prior to testing. Some had also recently received pooled random donor platelets. Approximately 5% to 10% of nonthrombocytopenic hospitalized patients have elevated levels of PAIgG, predominately in the range of 10 to 20 fg/platelet.

overall failure rates reported in studies in which only stable, selected patients were reported: 8%, 20%, 8%, and 13%.¹⁴⁻¹⁷ Thus, nonimmunologic factors unrelated to crossmatch, HLA-A,B and ABO may account for at most ~10% to 20% of transfusion failures in typical refractory patients. An exact estimate of the role of nonimmunologic factors in platelet transfusion failures is not possible from our data because we did not examine in detail the clinical factors that might cause unsatisfactory increments in crossmatch-negative transfusions.

Our crossmatch technique appears to be sensitive to HLA-A,B, ABO and platelet-specific antibodies such as anti-PIA¹. Therefore, it is surprising that for crossmatch-negative transfusions, HLA-A,B and ABO matching still played a significant role in predicting transfusion success. Negative crossmatches led to corrected increments of $\geq 7,500/\mu\text{L}$ at 1 to 4 hours posttransfusion in only 57% of cases. HLA-A,B matching alone yielded a 50% success rate. The simplest possible explanation would be that our crossmatch technique is not sufficiently sensitive to HLA-A,B antibodies. We believe that this is unlikely based on its ability to detect increases in platelet-bound IgG at the level of 50 to 100 IgG molecules per platelet,¹³ and our success in detecting HLA-A,B antibodies detected by lymphocytotoxicity techniques. However, we have not made an exhaustive study of this aspect of our assay. If our platelet crossmatch assay is insensitive to some HLA-A,B antibodies, this is also likely to be true of other published assays. Other laboratories using different methodologies but similar patient selection criteria have also found low success rates for crossmatch-negative HLA-A,B matched transfusions: 52% to 77% (Table 2).^{8,18-21} It is possible that clinically significant types of

NOTE. Comparison of results of studies in which the patients were "selected" to be free of factors known to compromise platelet recovery and survival after transfusion, such as sepsis, fever, bleeding, consumption coagulopathy, autoimmune thrombocytopenia, and splenomegaly, and studies in which all refractory patients were studied, without exclusions (ie, "unselected").

n, number of crossmatches performed; Positive (%), percentage of all crossmatches positive; Negative (%), percentage of all crossmatches negative; positive predictive value, percentage of transfusions with positive crossmatches that had unsatisfactory platelet count increments as defined by the authors; negative predictive value, percentage of transfusions with negative crossmatches that had satisfactory increments as defined by the authors; crossmatch method, primary serological technique used as crossmatch in the study.

Abbreviations: RIA, radioimmunoassay; ELISA, enzyme-linked immunosorbent assay; RBC-IA, RBC immune adherence; LCT-AHG, anti-human globulin-augmented lymphocytotoxicity; NR, not reported.

anti-platelet antibody are not readily detected by any of the existing techniques, including our own. Further study of this possibility is needed before definitive conclusions can be drawn about the role of crossmatching in refractory patients.

Transfusions of donor plasma containing ABO antibodies incompatible with the recipient's ABO antigens were associated with poorer platelet count increments in our study. Even in crossmatch-positive transfusions, HLA-A,B and ABO matching appeared to contribute to predicting post-transfusion platelet count increments. These findings cannot be explained by the insensitivity of the crossmatch used. Thus, the relatively disappointing performance of platelet crossmatching in our study and some of those previously reported^{8,18-21} are not due solely to nonimmunologic factors affecting platelet destruction or to the insensitivity of the crossmatch technique used. We suspect that the "false-negative crossmatches" are due to multiple factors in typical refractory patients.

One factor in a few instances might have been the dosage of platelets administered. A standard single donor platelet transfusion may be expected to raise the platelet count by 25,000 to 60,000/ μ L in a patient who is thrombocytopenic and without other reasons for decreased platelet recovery and survival. This corresponds to a corrected increment of 10,000 to 20,000/ μ L in a 1.7-kg adult given 4×10^{11} platelets. Thus, if platelet consumption is as little as 1.3 to 3 times normal due to splenomegaly, infection, bleeding, consumption coagulopathy, or a combination of these, the corrected increment might be $\leq 7,500/\mu$ L solely on the basis of inadequate dosage. Unfortunately, increasing the dosage of HLA-A,B matched single-donor platelets is both logistically difficult and extremely expensive. The importance of dosage is sup-

ported by our observation that 6 of the 15 satisfactory increments observed despite positive platelet crossmatches occurred in very small children receiving full adult dosages of platelets. Baldini and colleagues reported that giving very large dosages of incompatible platelets to children unresponsive to platelet transfusion could temporarily overcome their refractoriness.²²

A second possible explanation for false-negative crossmatches is that immunological causes of refractoriness exist other than antibody specific for platelet surface antigens. If this is so, it should not be surprising that in vitro assays such as crossmatching fail to predict in vivo results consistently. Indeed, our data show that in vivo findings, such as post-transfusion platelet count increments and level of IgG on circulating platelets, are not fully predicted by the results of crossmatching. Thus, additional hypotheses for immunologic mechanisms of platelet destruction in typical refractory patients are in order.

The additional causes of platelet destruction in refractory patients, not detectable by current crossmatch techniques, are probably immunologic. We base this conclusion on the important role that HLA-A,B matching and ABO matching appear to play in transfusions without detectable antiplatelet antibody. Also, our refractory patients universally had platelets coated with large quantities of IgG. This increased IgG may be due to previous incompatible platelet transfusions, as none of our patients received only crossmatch-negative, HLA-identical, and ABO-identical transfusions. Elevations in PAIgG were noted prior to transfusion and after both crossmatch-positive and crossmatch-negative transfusions. Thus, this IgG may be a nonspecific finding of no clinical significance. This increased IgG may also be due to immunologic mechanisms other than platelet-specific antibody

detectable in a crossmatch. Such immunologic mechanisms could be characteristic of the refractory state.

Two possibly relevant mechanisms are suggested by previous investigations of immune destruction of platelets due to drugs and microorganisms. Shulman and Jordan²³ and, more recently, Christie and Aster²⁴ demonstrated that platelets can acquire drug and IgG complexes by at least two pathways. One is the binding of IgG-drug complexes to platelet Fc receptors. The other is the binding of IgG, drug, and platelet in a complex that requires all three for antibody fixation on the platelet. Kelton and associates showed that the thrombocytopenia of malaria is due to acquisition of malarial antigens and the corresponding IgG antibody by the patient's platelets.²⁵ We propose that similar innocent bystander mechanisms involving soluble donor plasma HLA-A,B and ABO antigens may exist. This hypothesis is supported by our finding that, independent of the crossmatch result, HLA-A,B and ABO matching predict the posttransfusion platelet count increment. Platelets can acquire new blood group antigens such as HLA-A,B^{26,27} and ABO^{28,29} from plasma. Transfused plasma ABO and HLA-A,B antigens may affect platelet recovery and survival even when the platelet surface versions of these antigens are not detected in the crossmatch.

Paradoxically, transfusions of ABO-compatible platelets that are accompanied by ABO-incompatible plasma yield poor platelet count increments (eg, O platelets to an A recipient). This new finding requires confirmation. One hypothetical explanation for these results is that anti-A from the donor plasma combines with soluble A antigen in the recipient's plasma, and then damages the type O donor platelets by an immune-complex mechanism. Alternatively, the type O transfused platelets may acquire A antigen in the recipient's plasma and subsequently be injured directly by the anti-A from the donor. If such mechanisms exist, incompatible transfusions might affect the fate of subsequent transfusions that were otherwise immunologically compatible. Any role for plasma HLA-A,B and ABO antigens in platelet transfusion immunology remains speculative and will require further investigation.

If our preliminary results are confirmed by other researchers, the role of platelet crossmatching in typical refractory patients clearly may be more limited than has been expected. We and others had hoped that crossmatching would make HLA-A,B matching unnecessary and enable the use of

randomly selected crossmatch-negative pools of donor platelets. Our data do not provide much cause for optimism in this regard, at least in typical refractory patients. In our patients, crossmatch-negative C-matched platelets do reasonably well in the first few hours posttransfusion. However, later C-matched platelets appear to be considerably less likely to provide satisfactory platelet count increments than do A-, BU-, or BX-matched platelets. Some of this disadvantage may be overcome by using ABO-identical C-matched platelets. Our findings support a role for ABO in platelet transfusions, first studied by Aster ~20 years ago.³⁰ New data on possible roles for ABO³¹ and HLA-A,B³² matching have recently been reported by other investigators.

Our study has certain practical implications for changing the manner in which platelet donors are selected for refractory patients. If an IgG crossmatch technique is available and practical, it should be used to avoid transfusing donor platelets that are crossmatch positive with the recipient. Closely HLA-A,B-matched platelets should be given next priority. If C or worse grades of match are the only ones available, ABO identical donors should be selected if feasible. Our data suggest that an IgM crossmatch will not add significantly to the clinical benefit to be gained by crossmatching in most cases.

The alleviation of refractoriness in many patients may be quite difficult, if our results are typical. Further research into the multiple mechanisms of immunologic refractoriness to platelet transfusion is indicated, and efforts to prevent refractoriness^{33,34} warrant additional attention.

NOTE ADDED IN PROOF

Brand et al recently reported ABO antibodies as a cause of platelet refractoriness (*Transfusion* 26:463, 1986).

ACKNOWLEDGMENT

We thank Gerald Sage, Glenda Spencer, Deborah Polidori Schwartz, Kathy Lopez, Gail Smyth, and Judy Buechel for additional technical assistance. We thank the members of the Pheresis staff at the Rochester Region, American Red Cross Blood Services for their assistance in collecting platelet transfusions and clinical data. We thank the attending physicians and house staff throughout the area of New York State and Pennsylvania served by the Rochester Red Cross for assistance in obtaining appropriate patient specimens and sharing their clinical data with us. We thank Carol Cole and Dee Watts for secretarial and clerical assistance.

Identification of a Defective Factor XI Cross-Reacting Material in a Factor XI-Deficient Patient

By C. Mannhalter, P. Hellstern, and E. Deutsch

A homozygous factor XI-deficient girl, who appeared to be positive for cross-reacting material (CRM⁺) was studied for clarification. Factor XI antigen (F XI:Ag) was measured by radial immunodiffusion using monospecific, heterologous anti-factor XI antibodies. Factor XI coagulant activity (F XI:C) was determined in a modified activated partial thromboplastin time (APTT) test. The ratio of F XI:C to F XI:Ag was 0.04 for the proposita, as compared with 0.7 to 0.74 in the other family members. In contrast, 12 normal individuals had ratios of F XI:C to F XI:Ag of 1.04 ± 0.15 . F

FACTOR XI (plasma thromboplastin antecedent) deficiency is a rare hereditary blood coagulation disorder. Since the first report by Rosenthal in 1953,¹ several hundred cases have been recognized, most of them among Ashkenazi Jews.² Only a few well-documented cases have been observed in persons of non-Jewish origin.³⁻⁶ All publications to date agree that hereditary factor XI deficiency represents a genetic disorder and is caused by the absence of the molecule.⁷⁻⁹ Genetic heterogeneity of hereditary factor XI deficiency has been suspected, but has not yet been established. However, it deserves particular consideration, since factor XI-deficient patients differ greatly in their bleeding tendency.^{10,11} This article reports the studies of a patient with normal levels of factor XI antigen (cross-reacting material, CRM) and severely reduced clotting activity not due to a circulating antibody. The data elucidate the kind of this factor XI defect.

MATERIALS AND METHODS

All chemicals obtained from commercial sources were the best grade available. Micronized kaolin was generously supplied by Helena Laboratories, Beaumont, TX. Soybean trypsin inhibitor (SBTI) was purchased from Serva, Heidelberg, FRG. Corn trypsin inhibitor (CTI) was prepared according to the methods of Kirby and colleagues.¹² The protein concentration of our preparation was 1.5 mg/mL as determined by the Lowry method.¹³ The chromogenic substrate S-2366 was a generous gift of Kabi Vitrum, Stockholm. Radial immunodiffusion experiments were carried out with Seakem agarose from FMC, Rockland, ME. Anti-F XI antibodies were either a gift of Dr B.N. Bouma, Utrecht, Holland, or were obtained from Nordic, Tilburg, Holland. Anti-F XII antibodies were from Behring-Werke, Marburg, FRG. All reagents for polyacrylamide gel electrophoresis were purchased from Bio Rad, Richmond, CA. Nitrocellulose membrane (Hybond C) was obtained from Amersham, Buckinghamshire, UK. For autoradiography, Kodak S X-ray films and sapphire intensifying screens were used at -70°C .

Patients' Blood Samples

Samples were drawn from the antecubital vein using a 19-gauge butterfly needle. Nine parts blood were mixed with 1 part 0.1 mol/L of sodium citrate. Platelet-poor plasmas (PPPs) were obtained by 20-minute centrifugation at 2,000 g. The plasmas were aliquoted into 0.3-mL aliquots and stored at -20°C .

Coagulation Activities

Coagulation activities were assayed in a modified activated partial thromboplastin time (APTT) system using hereditary deficient

XI esterolytic activity was clearly higher than F XI:C in the proband, but not in her relatives. Immunoblotting studies demonstrated F XI CRM in the patient's plasma. Chromatography on diethylaminoethanol (DEAE)-Sephadex at pH 8.4 led to an almost complete removal of F XI from the plasma. The defective F XI was not bound to a negatively charged kaolin surface due to an abnormal interaction with high-mol-wt kininogen (HMWK).

© 1987 by Grune & Stratton, Inc.

plasmas as described previously.¹⁴ F XI- and F XII-deficient plasmas were obtained from Behring-Werke, prekallikrein (PK) and high-mol-wt kininogen (HMWK)-deficient plasmas were purchased from George King Bio-Medical, Overland Park, KS. If not mentioned otherwise, kaolin (Behring-Werke, 20 mg/mL of saline) was the activating surface. In selected experiments, ellagic acid (Actin; Merz and Dade, Düringen, Switzerland) was used as activating surface in the clotting assays following the manufacturer's instructions.

Esterolytic Activity of Factor XI

Esterolytic activity of factor XI was determined according to Scott and associates.¹⁵ In brief, plasma dilutions were treated with CHCl_3 to remove C1-esterase inhibitor. Activation of F XI was achieved with micronized kaolin (final concentration in the assay 0.5 mg/mL) in the presence of SBTI (5 $\mu\text{mol/L}$). After 30-minute incubation at 37°C , F XIIa was inhibited with CTI (final concentration 15 $\mu\text{g/mL}$). The esterolytic F XIa activity was quantitated at 405 nm by measurement of the cleavage of the chromogenic substrate S-2366 at 37°C . All plasma dilutions were made with F XI deficient plasma (Behring).

Antigen Concentrations

Antigen concentrations of F XI and F XII were measured by radial immunodiffusion (RID). The F XII antibody was used at 2%; the F XI antibody was used at 1.5% in 1% agarose. The incubation time needed to form distinct F XI-anti F XI precipitates was 24 hours at room temperature and 6 days at 4°C . The F XII plates were incubated for 24 hours at room temperature and 3 days at 4°C . After extensive washing, the immunoprecipitates were stained with Coomassie brilliant blue.

Kaolin-Binding Studies

For kaolin-binding studies, undiluted plasma samples were incubated with kaolin or micronized kaolin (final concentration 2.8 mg/mL) for 5 minutes at 37°C with repeated mixing. After centrifugation

From the First Department of Medicine, School of Medicine, Austria, and the Department of Haemostasis and Transfusion, University Homburg-Saar, FRG.

gation in a Beckman Microfuge B, the supernatants were tested for factor XI:Ag by RID. Control samples containing saline instead of kaolin were treated identically. RID was performed as described above.

Effect of Patient Plasma on Normal Plasma Factor XI Activity

We tested the presence of a factor XI inhibitor in the patient's plasma by incubation of a constant amount of patient plasma with varying amounts of normal plasma for 60 minutes at 37°C, followed by a determination of the F XI clotting activity.

Purification and Radiolabeling of F XI

F XI was purified from human plasma by sequential chromatography as described previously.¹⁹ The purified protein had a specific activity of 138 U/mg. This F XI was radiolabeled with immobilized lactoperoxidase (Radioiodination System; New England Nuclear, Dreieich, FRG) according to the manufacturer's instructions.

Electrophoretic Studies and Western Blot Analysis of Normal and Patient's Plasma Samples and Pretreated Plasmas

Pretreatment of the plasmas with diethylaminoethanol (DEAE)-Sephadex. Normal citrated plasma as well as the proposita's plasma were treated identically in the following ways: Plasma aliquots (50 mL) were dialyzed against 1 L Tris-succinic acid buffer (0.04 mol/L of Tris, 0.01 mol/L of succinic acid, 0.001 mol/L of EDTA, 0.001 mol/L of benzamidine, 0.02% sodium azide, 50 mg polybrene/L, pH 8.4) at room temperature overnight with two buffer changes. The dialyzed samples were applied to a DEAE-Sephadex column (2.5 × 37 cm) equilibrated with the same buffer. In normal plasma, the elution of factor XI from the column was monitored by determination of the factor XI clotting activity. F XI was found in the first protein peak passing through the column. In the patient's plasma, which lacked F XI:C, this first protein peak was pooled analog to normal plasma and used for further studies.

Kaolin Adsorption of the Plasmas. Aliquots of normal plasma, the proposita's plasma and a factor XI-deficient patient's plasma (200 µL each) were incubated with 32 µL of kaolin suspension (20 mg/mL of saline) for 5 minutes at 37°C. The samples were then spun for 1 minute in a Beckman Microfuge, washed with three times 1 mL of saline and eluted overnight with 120 µL 6% sodium dodecyl sulfate (SDS) in stacking gel buffer. After spinning for 1 minute in the Microfuge, 60 µL of each supernatant was applied to SDS-polyacrylamide gel electrophoresis (PAGE).

Electrophoretic separation on SDS gels. Samples were mixed with appropriate amounts of stacking gel buffer containing 6% SDS and treated for 3 minutes in a boiling water bath. The samples were separated on 7.5% SDS-polyacrylamide slab gels (1.5 mm thick) according to the method of Laemmli.¹⁷ Separation was carried out using constant current (35 mA/gel) and tap water cooling.

Blotting conditions. After electrophoresis, gels were immediately used for electroblotting onto nitrocellulose (Hybond C, Amersham) according to the general method of Towbin and colleagues.¹⁸ Proteins were electrotransferred at 1.5 V/cm overnight or 5 V/cm for 2 hours in a Tris-glycine buffer (25 mmol/L of Tris–190 mmol/L of glycine pH 8.3) at 10°C using a Bio Rad Trans-Blot system. After transfer, the nitrocellulose membranes were quenched with 0.4% gelatin–0.2% Tween–0.02% NaN₃ in phosphate-buffered saline (PBS) pH 7.2 for 4 hours. This solution was used in the following steps as medium for the antibody and the labeled F XI. The washing solution used throughout the procedure was PBS containing 0.2% Tween and 0.02% NaN₃. Immunodetection of the antigens blotted

onto nitrocellulose was achieved by interaction with an immunoadsorbed polyclonal goat–anti-human factor XI antibody for 16 hours. After three washes (15 minutes each), the bound factor XI antibody was traced with ¹²⁵I-factor XI (incubation for 4 hours), followed by three more washes (15 minutes each). All incubations were done at room temperature. The washed membranes were dried and set up for autoradiography at –70°C.

Immunoabsorption of goat–anti-human F XI antibody. A sheet of nitrocellulose (15 × 15 cm) was incubated with F XI-deficient plasma (1 mL in 25 mL of quenching buffer) for 4 hours at room temperature. The membrane was then quenched with gelatin as described above. One such sheet was used for immunoabsorption of 50 mL of a 2% antibody solution in quenching buffer.

Clinical information. A more detailed description of the patient is given in a previous article.¹⁹ In brief, the patient, a 12-year-old girl (G.S.) suffered from a lifelong tendency to develop large hematomas after trivial traumata. Severe bleeding occurred after dental extraction and after adenectomy. Her mother (G.K.) and her sister (G.E., aged 14 years) also experienced bleeding episodes, whereas the father (G.M.) did not. Jewish ancestry and consanguinity between the parents could be ruled out. Coagulation tests for F VIII and F IX, measurements of F VIII:Ag, F VIII:R:CoF, platelet adhesiveness, platelet aggregation, and template bleeding time were normal, as reported previously.¹⁹

RESULTS

Evaluation of Contact Phase Factors by Coagulation Assays

The clotting assays of the four contact factors at the time of the investigation exhibited normal activities of prekallikrein (PK) and high-mol-wt kininogen (HMWK) in all family members studied. The factor XI levels in the patient's plasma and her relatives' plasma had been evaluated at different times in Germany as well as in Austria. Factor XI:C data were obtained in 1984 in both laboratories from the same plasma source, and they correlated very well. They reflected reduced F XI levels in the mother and the proposita, and borderline F XI concentrations in the father (Table 1). However, when fresh blood samples were collected in 1985 and were assayed with F XI-deficient plasma (Behring) we obtained the following results. The factor XI activity in the proposita's and her father's plasma was similar to the first investigation. The mother's and the sister's plasma exhibited higher factor XI levels, within the normal range (Table 1). Interestingly, the determination of F XI:C with a different deficient plasma (Immuno) in the proposita's, her mother's, and her sister's plasma gave clearly lower F XI:C values (Table 2).

Table 1. Factor XI:C Data 1984 and 1985

Subject	1984 (U/mL)	1985 (U/mL)
Father	0.63	0.69
Mother	0.49	0.64
Sister	—	0.63
Proposita	0.02	0.04
Normal range	0.6–1.4	

Data for 1984 represent mean values of two different coagulation assays of blood samples. Data for 1985 represent mean values of two independent coagulation assays of blood samples analyzed with factor XI-deficient plasma, Behring.

Table 2. Clotting Activities and Antigen Concentrations of Contact Factors in Patients and Controls

Parameter (U/mL)	Proposita G.S.	Sister G.E.	Mother G.K.	Father G.M.	Normal Range
F XI:C (F XI dp Behring)					
Kaolin	0.04	0.63	0.64	0.69	0.6–1.4
Micronized kaolin	0.036	0.60	0.65	0.63	1.05*
Ellagic acid	0.086	0.60	0.67	0.70	1.07*

Kaolin	0.03	0.53	0.5	n.d.	—
Esterolytic F XI activity	0.17	0.51	0.57	0.52	0.76–1.1
F XI:Ag (RID)	0.89	0.89	0.86	0.98	0.6–1.36
Ratio F XI:C to F XI:Ag	0.04	0.71	0.74	0.7	0.87–1.11
F XII:C	0.32	0.85	1.4	0.69	0.56–1.96
F XII:Ag	0.4	0.87	1.4	0.58	0.45–2.14
Ratio F XII:C to F XII:Ag	0.8	1.0	1.0	1.2	—
HMWK:C	0.92	1.05	1.1	1.02	0.78–1.42
PK:C	1.3	1.4	1.42	1.4	0.85–1.95

Kaolin was used in a concentration of 20 mg/mL of saline. Micronized kaolin was adjusted to 5 mg/mL. Actin (Merz & Dade, Düringen, Switzerland) served as the source for ellagic acid.

*Value obtained with reference plasma 100% (Immuno AG, Vienna).

The first determinations of F XII:C were done only in Germany, using a one-stage F XII:C assay. According to these results, father, sister, and proposita appeared to have heterozygote factor XII deficiencies. During the follow-up study, the fresh blood samples obtained in 1985 were investigated in Austria by a two-stage F XII:C assay and F XII:Ag determinations. Interestingly, only the proposita's plasma was deficient in F XII:C and F XII:Ag with these assay systems on this occasion (Table 2).

Effect of Patient Plasma on Normal Plasma F XI Clotting Activity

No inhibitory activity of the proposita's plasma on normal plasma F XI could be discovered, as shown in Table 3.

Determination of F XI:Ag and F XII:Ag

All F XI-antigen determinations were carried out at least once with Bouma's antibody and once with the commercial antibody (Nordic) for comparison. Since no difference in the results was observed, all repeat experiments were performed with the easily accessible commercial product. F XI:Ag determined by RID was normal in all family members. The ratio of F XI:C to F XI:Ag was 0.04 in the proposita, 0.74 in

the mother, 0.7 in the father, and 0.71 in the sister. Comparison of F XI:C to F XI:Ag in 12 normal controls gave ratios between 0.87 and 1.11 (mean value 1.04 ± 0.15 , Table 2). Evaluation of F XI:Ag by neutralization-inhibition assay gave similar results, as published previously.¹⁹ F XII:Ag, measured by RID, was low in the patient, but normal in the other family members. The ratio of F XII:C to F XII:Ag was between 0.8 and 1.2 (Table 2).

Esterolytic Activity of F XI

Application of the chromogenic substrate method for measurement of factor XI activity gave good results when all sample dilutions were made with F XI-deficient plasma. Using this method of sample dilution, cleavage of S-2366 by any component other than factor XI was identical in all samples. Various mixtures of normal plasma and F XI-deficient plasma were evaluated (Table 4). Correct determinations of F XI above concentrations of 0.1 U/mL were possible with good correlation of the results with the clotting assay. However, if samples containing <0.1 U F XI/mL were assayed, eg, undiluted F XI-deficient plasma, determination of the esterolytic activity gave higher values than the clotting assay.

The values of the F XI:esterolytic activity in the patient's and her relatives' plasmas are shown in Table 2. According to these results, all family members were below the normal range.

Activation of F XI With Ellagic Acid and Micronized Kaolin

When micronized kaolin was used for the activation of F XI:C, the results were the same as with normal kaolin. However, with ellagic acid the estimated XI:C activity in the proposita was twice as high as with kaolin (Table 2). The reason for this phenomenon is presently unclear.

Effect of Kaolin on Normal and Patient's F XI

Incubation of normal plasma samples with kaolin resulted in fast (<5 minutes) removal of F XI antigen from the plasma supernatant. In contrast, the F XI antigen was still demonstrable in the patient's plasma supernatant (Fig 1). The father's F XI interacted normally with kaolin, whereas the mother's (Fig 1) and the sister's (Fig 2) F XI antigen was

Standard curves were prepared with a standard reference plasma diluted with factor XI-deficient plasma.

Fig 1. Radial immunodiffusion (RID) of kaolin-treated plasma supernatants. Undiluted plasma samples (100 μ L) were incubated with either 16 μ L of kaolin (20 mg/mL of saline) or 16 μ L of saline for 5 minutes at 37°C. Kaolin was separated by centrifugation for 2 minutes in a Beckman Microfuge B. Of each supernatant, 60 μ L was applied to 1% agarose plates containing 1.5% F XI antibody, and RID was carried out as described in the Materials and Methods Section. Samples, left to right: C, control plasma, G.S., proposita, G.M., father, G.K., mother.

not completely removed from the supernatant by kaolin. In HMWK-deficient plasma, studied as a control, the factor XI antigen did not interact with kaolin (Fig 2), as was expected.

Immunoblotting of Factor XI in Normal Plasma and Patient's Plasma

Samples containing 6 μ L of plasma were electrophoresed in a discontinuous buffer SDS-PAGE system and electrotransferred onto nitrocellulose. When they were reacted with the polyclonal F XI antibody followed by ^{125} I-factor XI, the autoradiograph showed essentially identical patterns in normal and patient's plasma (Fig 3). Four bands could be identified. One band, migrating with a mol wt of $\approx$ 130 kd, corresponded to purified factor XI. A second band, mol wt $\approx$ 160 kd, represented IgG. The other two bands could be identified in control experiments (data not shown) as HMWK, which ligated with ^{125} I-factor XI during the second incubation reaction.

Immunoblotting of Factor XI in Samples Passed Through DEAE-Sephadex A-50 Columns

Samples containing 60 μ L of the protein pool unbound by DEAE-Sephadex at pH 8.4 were used for SDS electrophoresis.

When normal plasma was chromatographed, these samples were pooled according to the F XI content determined in a clotting assay. When patient plasma was passed through the column, monitoring of the clotting activity was impossible due to starting activity that was too low. Therefore, the protein peak not bound to the column was pooled.

The samples were electrophoresed as described. The gels were electroblotted onto nitrocellulose and incubated with F XI antibody and ^{125} I-F XI. Figure 4 shows the results of the autoradiograph. In the normal material, a distinct band, corresponding to purified F XI, was present at mol wt $\approx$ 130 kd. A second diffuse band represented IgG. The two bands observed in plasma and identified as HMWK were no longer visible, which was not surprising since HMWK is known to bind to DEAE-Sephadex at pH 8.4. In the patient's plasma,

Fig 2. Radial immunodiffusion (RID) of kaolin-treated high-mol-wt kininogen (HMWK)-deficient plasma's supernatant. HMWK-deficient plasma (100 μ L) was treated with 16 μ L of kaolin (20 mg/mL of saline) or saline for 5, 10, and 30 minutes at 37°C. After centrifugation for 2 minutes in the Microfuge, 60 μ L of the supernatant was submitted to RID. Normal control plasma (C) and plasma of G.E. (proposita's sister) were treated identically before application to the RID plate.

only a very weak band migrating with mol wt $\approx$ 130 kd and corresponding to purified F XI could be distinguished. The band representing IgG was present in concentrations similar to those in the normal material. HMWK was also removed by DEAE-Sephadex at pH 8.4.

Fig 3. Immunoblotting of F XI in citrated plasma using 2% F XI antibody and ^{125} I-F XI overlay technique. Sixty-microliter aliquots of 1:10 diluted plasma were treated with 36 μ L of sodium dodecyl sulfate (SDS) and subjected to SDS-polyacrylamide gel electrophoresis (PAGE) and immunoblotting. Lane 3, G.S. plasma; lane 2, normal plasma, lane 1, purified F XI (2 μ g). Autoradiographs were exposed for 240 hours at -70°C .

Fig 4. Immunoblotting of F XI in diethylaminoethanol (DEAE)-Sephadex-treated samples. Plasma samples were chromatographed on DEAE-Sephadex as described in the Materials and Methods section. Sixty-microliter aliquots of the unbound protein fraction of normal plasma (lane 2) and plasma of G. S. (lane 3) were treated with 36 μ L of 6% sodium dodecyl sulfate (SDS) and subjected to SDS-polyacrylamide gel electrophoresis (PAGE) and immunoblotting using 2% F XI antibody and ^{125} I-F XI overlay technique. Lane 1 contained purified F XI (5 μ g). Autoradiographs were exposed for 110 hours at -70°C .

Immunoblotting of F XI in Kaolin Eluates

After incubation with kaolin, normal, the proposita's, and a F XI-deficient patient's plasma samples were centrifuged in a Microfuge. The kaolin pellets were washed and then eluted with SDS as described in the Materials and Methods section. Aliquots, containing 60 μ L of each kaolin eluate were subjected to SDS-PAGE and immunoblotting. Results are shown in Fig 5. F XI and/or F XIa, as well as cleaved HMWK, were present in the kaolin eluate from normal plasma. In the kaolin eluate of the proposita and the F XI-deficient patient, only cleaved HMWK could be observed.

DISCUSSION

Hereditary deficiencies of coagulation factors can be caused either by the absence of a clotting protein or by the synthesis of a defective molecule. For hereditary factor XI deficiency, present data agree that the protein is absent in these patients.^{8,9,11,15} Only one publication mentions two

Fig 5. Immunoblotting of F XI in kaolin eluates using 2% F XI antibody and radiolabeled antigen (^{125} I-F XI) overlay technique. Lanes 2 through 4 contained 60 μ L of sodium dodecyl sulfate (SDS) eluates obtained from kaolin (320 μ g) adsorbed with 100 μ L of plasma (described in the Materials and Methods section). Lane 2, normal plasma; lane 3, G.S.; lane 4, factor XI-deficient patient. In lane 1, purified F XI (3 μ g) was run for comparison. Autoradiographs were exposed for 68 hours at -70°C .

patients, both of German origin, who apparently were positive for CRM.¹¹ Our report describes a German girl of non-Jewish ancestry with severe F XI:C deficiency but normal levels of F XI:Ag. Because a dysform of factor XI is a genetic rarity, our studies tried to confirm and elucidate the nature of the defect. Investigation of the effect of patient plasma on normal plasma ruled out an acquired or inherited inhibitor, which would have explained the phenomenon. General clotting tests and platelet function studies, carried out previously,¹⁹ showed that the only abnormalities were a mildly reduced F XII:C and a severely reduced factor XI:C. The factor XII:C level corresponded well with the factor XII:Ag, and therefore no further investigations of this protein were performed.

To shed some light on the patient's PTA defect, we studied the enzymatic properties of the factor XI protein in a chromogenic substrate assay. The study disclosed a fourfold higher esterolytic than clotting activity in the proposita. In contrast, in the other family members, the clotting activity was in the same range as the esterolytic activity. We believe that the observed elevation of F XI:est over F XI:C activity in the proposita's plasma is not an artifact, since we could accurately determine F XI:est activities >0.1 U/mL. The apparent F XI activity of 0.067 U/mL that we found in F XI-deficient plasma could not be inhibited by increased amounts of SBTI or CTI in the incubation mixtures, and its source is presently unknown.

The interesting phenomenon of a higher esterolytic than clotting activity in the plasma of G.S. may have various causes. First, the proband's molecule could be structurally defective and therefore no longer able to activate its natural substrate, factor IX, while it still cleaves the chromogenic substrate. Our results do not rule out this possibility.

Second, the reduced F XII level in the patient's plasma may have affected the clotting assay more than the esterolytic test, but did not. Reconstitution of the patient's plasma with purified F XII to normal concentration did not result in an increase of F XI:C activity.

Third, the defect in the proband's F XI molecule may have made an interaction with either HMWK and/or the negatively charged surface (kaolin) impossible. As a consequence, factor XI would remain in solution, and its activation by factor XIIa would occur at a slower rate. The six times longer activation time in the esterolytic test (30 minutes v 5 minutes in the clotting assay) could allow an increased generation of F XIa. Unfortunately, the incubation time of the clotting assay cannot be prolonged due to the presence of all natural inhibitors. Inactivation of the inhibitors by pretreatment of the plasma with CHCl_3 as used in the esterolytic test, is not applicable in the clotting assay. Thus, an approximation of the incubation time of both assay systems cannot be achieved.

Our observation that F XI antigen was not adsorbed to kaolin from G.S.'s plasma indicated that some binding properties of the F XI molecule were defective. Because binding of F XI to HMWK is required for the adsorption of F XI from plasma to negatively charged surfaces,^{20,23} the defect appeared to be due to an impaired F XI-HMWK complex formation.

To appreciate the interaction of the patient's F XI with HMWK and surface, performance of direct binding experiments with purified proteins would be important. Presently, however, we do not have enough plasma for purification of this abnormal protein.

A direct examination of the material adsorbed onto the kaolin surface was accomplished by SDS-PAGE and immunoblotting of kaolin eluates (Fig 5). In normal plasma, we could demonstrate adsorption of F XI and HMWK onto kaolin. HMWK was found in the kaolin eluate in its cleaved form and migrated as two close bands with a mol wt of ≈ 95 kd in unreduced samples. F XI and/or F XIa was identified as one band with an apparent mol wt of ≈ 150 kd in the unreduced eluates.

In the kaolin eluates of the *proposita*, only HMWK was present, and it exhibited the same electrophoretic behavior as in normal plasma. This observation confirmed our previous results obtained by RID which showed that F XI-antigen was not removed from plasma of G.S. by kaolin. The immunoblotting data that prove normal kaolin binding of HMWK support our hypothesis that the F XI molecule is unable to bind to HMWK and thus is not adsorbed to the kaolin surface. In the kaolin eluate of the truly F XI-deficient patient's plasma, only HMWK was demonstrable, as was expected.

The critical proof of the presence of an inactive F XI in the plasma of the *proposita* was approached not only by RID, but

also by immunoblotting studies. Immunoblotting studies of complex protein mixtures, eg, plasma, are difficult, especially if a trace protein such as F XI is detected. Therefore, in the case of F XI, the polyclonal antibody was preadsorbed with F XI-deficient plasma, previously immobilized onto nitrocellulose membranes, to remove contaminating antibodies not directed against F XI. Because this pretreatment alone was not sufficient to eliminate all nonspecific bands, a radioactive overlay technique using ^{125}I -FXI was applied as described by Lämmle and colleagues.²⁴ This technique improved the specificity of the method and allowed detection of F XI in a volume of 6 μL of plasma. Similar concentrations of F XI with the same electrophoretic migration behavior were present in the plasma of the *proposita* and in a normal control plasma (Fig 3). In both plasmas, the incubation of the blot with ^{125}I -F XI resulted in the appearance of two bands representing HMWK. The reason for this phenomenon is the complex formation between HMWK and F XI, a well-established reaction.²⁰ The observation of a normal complex formation between the patient's HMWK and purified ^{125}I -F XI clearly shows that the patient's HMWK has normal F XI binding properties. Therefore, the binding defect must be located in the F XI molecule.

Interestingly, in both plasma samples, a band corresponding to human IgG was visible, even when the ^{125}I -F XI overlay technique was used. The IgG band and the two HMWK bands were also seen in a control experiment in which a plasma blot, not treated with antibody, was incubated with ^{125}I -F XI. Thus, it appears that F XI not only complexes with HMWK but also attaches to IgG. Further experiments to study this phenomenon are necessary.

When normal and patient plasma were chromatographed on DEAE-Sephadex at pH 8.4 and the unadsorbed protein fractions were analyzed on SDS-PAGE followed by immunoblotting, we made an interesting observation. In normal plasma, F XI as well as IgG did not bind to DEAE-Sephadex at pH 8.4, and both bands could be identified on the autoradiograph (Fig 4). In contrast, in the plasma of the *proposita*, IgG passed through the column unadsorbed, whereas F XI apparently was removed by DEAE-Sephadex. We cannot yet show data that prove the binding of F XI to DEAE-Sephadex, however. Experiments to confirm these results are in progress.

An attempt to demonstrate F XI in the plasma of G.S. by Laurell immunoelectrophoresis was not successful (data not shown); no rockets could be obtained. The inability of the F XI of the *proposita* to form a complex with HMWK explains these results. F XI does not migrate under the conditions used in the Laurell techniques unless it is bound to HMWK.²⁵

The defective surface adsorption properties in the proband's factor XI molecule are a very interesting phenomenon, which may lead to better insights into the factor XI-HMWK-surface interactions.

Anemia of the Belgrade Rat: Evidence for Defective Membrane Transport of Iron

By Barbara J. Bowen and Evan H. Morgan

The mechanisms underlying the impaired utilization of transferrin-bound iron by erythroid cells in the anemia of the Belgrade laboratory rat were investigated using reticulocytes from homozygous anemic animals and transferrin labeled with ^{59}Fe and ^{125}I . The results were compared with those obtained using reticulocytes from phenylhydrazine-treated rats and iron-deficient rats. Each step in the iron uptake mechanism was investigated, ie, transferrin-receptor interaction, transferrin endocytosis, iron release from transferrin, and transferrin exocytosis. Although there were quantitative differences, no fundamental difference was found in any of the abovementioned aspects of cellular function when the reticulocytes from Belgrade rats were

compared with those from iron-deficient animals. The basic defect in the Belgrade reticulocytes must therefore reside in subsequent steps in iron uptake, after it is released from transferrin within endocytotic vesicles, ie, in the mechanism by which it is transferred across the lining membrane of the vesicles into the cell cytosol. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of reticulocyte ghosts extracts demonstrated a prominent protein band of mol wt 69,000 that was absent or present only in low concentration extracts from the other two types of reticulocytes. This may be a result of the genetic defect.

© 1987 by Grune & Stratton, Inc.

THE BELGRADE laboratory rat suffers from hereditary microcytic, hypochromic anemia inherited as an autosomal recessive trait. The anemia is accompanied by reticulocytosis, elevated plasma iron and iron-binding capacity, decreased stainable iron in the tissues, and decreased growth rate.^{1,2} Iron uptake from transferrin by erythropoietic cells is diminished and globin synthesis is defective.^{1,3-5} The mechanisms underlying the impaired utilization of iron are unknown.

From results obtained in previous investigations using reticulocytes and transferrin labeled with ^{125}I and ^{59}Fe , it was concluded that uptake of the transferrin-iron-receptor complex is unimpaired and that the abnormality of iron incorporation probably resides in defective release of iron from transferrin within endocytotic vesicles. However, examination of the transferrin uptake curves presented in this article suggests a decreased rate of uptake by Belgrade reticulocytes when compared with those from control animals. If this is true, abnormal transferrin-receptor interaction or impaired endocytosis of the transferrin-receptor complex may be responsible. No investigations of the affinity of the receptors for transferrin have been published. Endocytosis of transferrin by Belgrade reticulocytes was studied by electron microscopy using antitransferrin labeled with ferritin.⁶ However, this investigation did not allow the rate of endocytosis to be measured. Moreover, even if transferrin-receptor interaction and the rate of endocytosis are normal, the defect in iron uptake could be due to defective transport of iron across the

endocytotic vesicle membrane instead of an abnormality of iron release from transferrin, as has been proposed.⁵

The aim of the present investigation was to resolve the above questions by studying each stage in the process of iron uptake by reticulocytes, ie, transferrin-receptor interaction, endocytosis, iron release from transferrin, membrane transport of iron, and exocytosis of transferrin.⁷ Early in this work, it became apparent that the appropriate control for studies with Belgrade reticulocytes is iron-deficient reticulocytes rather than those from iron-replete animals. Hence, the investigation was extended to include studies with reticulocytes from iron-deficient rats. The results indicate that the basic defect in the Belgrade reticulocyte lies in the mechanism of iron transfer across the lining membrane of endocytotic vesicles.

MATERIALS AND METHODS

Animals. Heterozygous (b/-) male and female Belgrade rats were very kindly provided by Dr John A Edwards, Department of Medicine, State University of New York at Buffalo. These animals were used to produce a colony of anemic (b/b) and nonanemic (b/-, +/-) animals. During the first 3 months of life and during pregnancy, the anemic animals were given frequent intraperitoneal (IP) injections of fresh blood from nonanemic rats of the same strain to reduce the high mortality that results from the severe anemia. The animals were fed a standard laboratory rat diet.

Iron deficiency was produced in 3-month-old male nonanemic Belgrade rats by the removal of 5 mL of blood by heart puncture on four occasions at 1-week intervals while maintaining the rats on an iron-deficient diet.⁸ The animals were then kept on this diet for a further 2 months, being bled only as required for the studies described below.

Reticulocytosis was also induced in nonanemic (b/- and +/-) rats by a single IP injection of neutralized phenylhydrazine HCl (10 mg/100 g of body weight). The animals were bled by heart puncture (2 mL/100 g of body weight) 5 days later and again 2 days after the first bleed. This second sample of blood was used for the experiments described in this article. In one experiment, reticulocytosis was induced solely by bleeding by heart puncture (2 mL/100 g of body weight) three times in 1 week of (+/-) rats that had been injected intramuscularly (IM) with 50 mg iron as iron-dextran 1 week before the first bleed. Blood was obtained 3 days after the last bleeding for the iron uptake studies.

For brevity, the reticulocyte-rich blood cells from homozygous Belgrade (b/b) rats, heterozygous (b/-) rats, iron-deficient (+/-)

rats, and phenylhydrazine-treated (?/–) rats are referred to as Belgrade, heterozygous, iron-deficient, and control reticulocytes, respectively.

Purifications and labeling of transferrin. Rat and rabbit transferrins were isolated from plasma by ion-exchange chromatography on diethylaminoethyl (DEAE)-cellulose (DE52, Whatman) and gel filtration with Ultrogel ACA34 (LKB).⁹ The rat transferrin was labeled with ⁵⁹Fe and ¹²⁵I as described previously.⁹ It was used in the diferric form in the experiments described below. The rabbit transferrin was used in cold-chase experiments and in the preparation of antisera in goats by three intramuscular injections of 5-mg quantities of the protein in Freund's complete adjuvant at 2-week intervals.

Isolation of transferrin receptor. The transferrin receptor was isolated from the placentas of control rats on the nineteenth day of gestation. The placentas from four pregnant rats were washed with several changes of phosphate-buffered saline (PBS) and then homogenized with 3 vol of PBS using a Potter-Elvehjem homogenizer. The insoluble components of the placentas were sedimented by centrifugation for 30 minutes at 40,000 g (average) and washed three times by resuspension in PBS and centrifugation as before. They were then treated with 2% Triton X-100 (Sigma, St Louis), 1 mmol/L of iodoacetic acid, 1.0 mmol/L of phenylmethylsulfonyl fluoride in PBS for 1 hour, followed by centrifugation at 40,000 g (average) for 1 hour. The transferrin receptor was isolated from the supernatant solution by affinity chromatography using rat transferrin coupled to Sepharose 4B (Pharmacia, Piscataway, NJ) following the procedure described by van Driel and colleagues.¹⁰ The isolated receptor was contaminated with rat transferrin, which was largely removed by passage through a Sepharose 4B-anti-rat transferrin column equilibrated and washed with PBS, pH 7.4-0.2% Triton X-100. All procedures were performed at 4°C.

Measurement of transferrin and iron uptake. Blood was obtained from the anemic rats by heart puncture, using heparin as an anticoagulant. The cells were washed three times with ice-cold PBS and were then suspended in Hanks' and Wallace balanced salt solution. The buffy coat was removed from the RBC layer at the end of each wash. After the third wash, the cells were centrifuged at 2,000 g for 30 minutes at 4°C and the top one-quarter of the RBC layer was removed to obtain a reticulocyte-enriched cell suspension. These cells were suspended in Hanks' solution. The reticulocyte counts of these suspensions varied from 20% to 38% for the Belgrade reticulocytes, 21% to 49% for heterozygous reticulocytes, 22% to 59% for control reticulocytes and 18% to 37% for iron-deficient reticulocytes.

Aliquots of the reticulocyte suspensions were then incubated with ¹²⁵I-⁵⁹Fe-labeled transferrin, washed with ice-cold PBS and treated with Pronase (Calbiochem-Boehringer, San Diego) at 4°C to measure endocytosed transferrin as previously described.¹¹ Transferrin and iron exocytosis were measured by a cold-chase procedure, again using incubation with Pronase at 4°C to distinguish between membrane-bound and intracellular transferrin.¹¹ The validity of this method for the measurement of transferrin endocytosis has been demonstrated by quantitative electron microscope autoradiography.¹² To measure the number and affinity of transferrin receptors on the cell surface, samples of the cells were incubated for 30 minutes at 4°C with varying concentrations of radiolabeled transferrin in the presence of 10 mg/mL of bovine serum albumin (BSA) (Sigma, St Louis, Type A7030). Total cell-associated transferrin was then determined by centrifuging 150-μL aliquots of the cell suspension through a mixture of di-n-butyl phthalate and dinonyl phthalate (2:1; vol:vol) in a Beckman Microfuge for 15 seconds, and counting the resultant cell pellet for radioactivity. Nonspecific binding of transferrin was measured in duplicate incubations con-

taining a 50-fold molar excess of unlabeled diferric rat transferrin. Specific binding was calculated as the difference between total and nonspecific binding, and was used to estimate the numbers of specific receptors on the cell membrane (B_{max}) and the association constant of the transferrin-receptor reaction (K_a) by Scatchard method.¹³ The total number of cellular receptors was measured in a similar manner except that the incubations were performed at 37°C. The percentage of total receptors situated on the cell membrane was calculated from these values.

Analytical procedures. Reticulocytes were determined by staining with new methylene blue, packed cell volume by the microhematocrit procedure and mean corpuscular volume (MCV) by the use of an automated cell counter (Model H.1; Technicon, Terrytown, NY). Heme was extracted from washed cells by the method of Thunell.¹⁴ Radioactivity was counted in a three-channel γ-scintillation counter. Polyacrylamide gel electrophoresis (PAGE) was performed as described by Laemmli,¹⁵ using 10% polyacrylamide in the resolving gel, and reducing the samples by heating to 95°C in sample buffer containing 4% sodium dodecyl sulfate (SDS) and 10% mercaptoethanol. The samples were run in duplicate. One set of the duplicates was stained for protein using Coomassie brilliant blue R250. The transferrin receptor was identified in the other set of the duplicates by Western blot transfer of the proteins from the polyacrylamide gel to nitrocellulose membrane and by staining with anti-rat transferrin receptor serum, followed by reaction with goat anti-rabbit IgG coupled to horseradish peroxidase (Bio-Rad, Richmond, CA). The anti-rat transferrin receptor serum was produced in rabbits by injection of three doses of 100 μg of the receptor in Freund's complete adjuvant. The antiserum was cleared of contaminating anti-rat transferrin by passage through a column of transferrin coupled to Sepharose 4B.

RESULTS

Transferrin receptors. The affinities and numbers of transferrin receptors on Belgrade, iron-deficient, and control reticulocytes are given in Table 1. There were no significant differences ($P > .05$) between the K_a values for any of the three types of cells. Although the mean number of total sites per cell was significantly higher for the control reticulocytes than for the other two types ($P < .001$), the numbers on the outer cell membrane showed no significant differences ($P > .05$). Belgrade and iron-deficient reticulocytes had higher percentages of their total receptors on the cell membrane (57% and 69%), respectively, than did the control reticulocytes (30%). This difference was confirmed in experiments in which measurements were made before and after

Table 1. Transferrin Receptor Affinities (K_a) and Numbers on Outer Cell Membrane, and Total Receptor Numbers for Belgrade, Iron-Deficient, and Control Reticulocytes

Reticulocytes	Transferrin Receptors		
	K_a (M^{-1}) ($\times 10^{-6}$)	Numbers (Molecules/Cell $\times 10^{-4}$)	
		Outer Cell Membrane	Total
Belgrade	8.10 $\pm$ 1.25(3)	2.60 $\pm$ 0.23(7)	3.81 $\pm$ 0.42(7)*
Iron-deficient	7.13 $\pm$ 0.80(3)	2.86 $\pm$ 0.33(5)	5.00 $\pm$ 0.46(5)*
Control	7.87 $\pm$ 1.32(3)	2.85 $\pm$ 0.28(7)	9.66 $\pm$ 0.61(7)

Each value is the mean ($\pm$ SEM) of the number of measurements shown in parentheses. The K_a values and outer membrane receptor numbers were obtained by incubation of cells with ¹²⁵I-labeled transferrin at 4°C, and the total receptor numbers were obtained by incubation at 37°C (described in text).

*Significant difference from control reticulocytes, $P < .01$.

incubating reticulocytes with Pronase at 4°C to remove surface receptors. This produced only a 22% reduction in total receptor numbers on the control reticulocytes but 55% and 71% reductions for the iron-deficient and Belgrade reticulocytes, respectively (means of two experiments). The total number of receptors in the three types of reticulocytes correlated to some extent with the mean MCV values, which were 21, 27, and 85 fL for the Belgrade, iron-deficient, and control reticulocytes, respectively. The MCV of mature erythrocytes from untreated nonanemic rats was 59 fL.

In the one experiment in which reticulocytes from the rats that had been bled >1 week after receiving an iron-dextran injection were used, the K_a and receptor number values and the rates of iron and transferrin uptake were similar to those from the control reticulocytes.

The transferrin receptors were also examined by SDS-PAGE (Fig 1). The receptors from all cell types, including known heterozygous (B/−) rats), were identified as two closely opposed bands of similar mol wt, ~92,000. Although not evident in Fig 1, in some electrophoretic runs the Belgrade (B/B) receptor bands were of slightly faster mobility than the receptor from control reticulocytes. However, in these cases the receptor from the iron-deficient reticulocytes had mobility identical to that from the Belgrade cells. Hence, the change observed with the Belgrade reticulocytes appeared to be a consequence of iron-deficient erythropoiesis rather than of a genetic defect.

Several other differences were noted between the electrophoretic patterns of extracts from the ghosts of Belgrade and control reticulocytes. However, the same differences, with one exception, were noted when extracts of iron-deficient ghosts were compared with controls. The exception was the appearance of a strong protein band of approximate mol wt 69,000 in the Belgrade extracts as compared with its absence or near absence in the extracts from the other two types of

Fig 1. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis and immunochemical staining of the transferrin receptors after Western blot transfer to a nitrocellulose membrane of Triton X-100 extracts of the ghosts of iron-deficient (A), Belgrade (B), control (C), and heterozygous (D) reticulocytes. The cells were hemolysed with 15 mM phosphate buffer and washed three times in the same buffer; the ghosts were then extracted with 2% (wt:vol) Triton X-100 in the buffer. The Triton X-100 extract was centrifuged at 40,000 g for 1 hour at 4°C, and the supernatant was used for electrophoresis. Asterisks indicate the protein present in high concentration only in extracts of Belgrade reticulocytes. The transferrin receptor is the double band at the 92.5-mol wt position as shown by Western blot.

reticulocytes including those from heterozygous (+/−) Belgrade rats (Fig 1).

Transferrin endocytosis and iron uptake. The rates of transferrin endocytosis and iron uptake were measured in eight separate experiments comparable to the one shown in Fig 2. As noted by earlier investigators, the outstanding feature was the relatively slow rate of iron uptake by Belgrade reticulocytes, even when compared with iron-deficient animals. Transferrin endocytosis was also slower in the Belgrade reticulocytes, but the relative decrease was not as great as that of iron uptake. This is illustrated very clearly by comparison of the mean rates of iron uptake and transferrin endocytosis in these experiments (Table 2). The mean rates of iron uptake obtained for the control and iron-deficient reticulocytes were almost twice those of transferrin endocytosis (Table 2), indicating that each molecule of diferric transferrin donated both its iron atoms to the cells during each intracellular cycle, as has been reported previously for rabbit reticulocytes.¹¹ However, with Belgrade reticulocytes the mean rate of iron uptake was only 0.7 times that of transferrin. Hence, on the average, only ~35% of the iron carried into the cells by endocytosis of transferrin was being retained by the cells. Incorporation into heme of the iron taken up by the cells was also measured. The proportion of iron incorporated into heme during 30-minute incubation at 37°C was much lower for the Belgrade and Fe-deficient cells (9% to 30%) than for the controls (39% to 81%).

Two other experiments using agents known to affect the rates of transferrin endocytosis and iron uptake, phorbol 12-myristate 13-acetate (PMA)¹⁶ and hemin,¹⁷ were also performed. PMA produced increases in the rates of transferrin endocytosis by all three types of cells (Table 3). In control and iron-deficient reticulocytes, this was accompanied by an increase in the rate of iron uptake, but with Belgrade reticulocytes no such increase was observed. In contrast, hemin inhibited transferrin endocytosis, and the degree of inhibition was greater with the control reticulocytes than with the other two types. In iron-deficient cells, the rate of iron uptake was inhibited to almost the same

Fig 2. Iron (A) and transferrin (B) uptake by control (●), iron-deficient (○), and Belgrade reticulocytes (▲). Internalization of iron and transferrin during incubation at 37°C with 2.5 μ mol/L ^{59}Fe - ^{125}I transferrin is shown. The reticulocyte counts were 25% for the control reticulocytes and 28% for the other two types of cells.

Table 2. Rates of Iron Uptake and Transferrin Endocytosis and the Ratio of Two Measurements for Belgrade, Iron-Deficient, and Control Reticulocytes

Reticulocytes	Iron Uptake (Atoms/Cell/ min $\times 10^{-4}$)	Transferrin Endocytosis (Molecules/Cell/ min $\times 10^{-4}$)	Iron:Transferrin
Belgrade	$0.68 \pm 0.082^{*}\dagger$	$1.05 \pm 0.21\dagger$	$0.65 \pm 0.13^{*}\dagger$
Iron-deficient	$2.33 \pm 0.69\dagger$	1.18 ± 0.31	1.97 ± 0.56
Control	4.05 ± 0.47	2.10 ± 0.25	1.93 ± 0.35

Each value is the mean ($\pm$ SEM) of eight measurements with Belgrade and control reticulocytes and five measurements with iron-deficient reticulocytes.

*Significant difference from control reticulocytes, $P < .01$.

$\dagger$ Significant difference from iron-deficient reticulocytes, $P < .01$.

$\ddagger$ Significant difference from control reticulocytes, $P < .05$.

degree as that of transferrin endocytosis. However, with Belgrade reticulocytes there was little change in the rate of iron uptake. Hence, the rate of iron uptake relative to that of transferrin endocytosis increased considerably (Table 3).

The rates of transferrin endocytosis and iron uptake were also measured in two experiments in which heterozygous reticulocytes were compared with Belgrade and control cells. The results confirmed the abovementioned differences between Belgrade and control reticulocytes but showed no differences between control and heterozygous reticulocytes.

Transferrin exocytosis and iron release from reticulocytes. The rates of transferrin exocytosis and iron release from reticulocytes labeled with ^{59}Fe and ^{125}I -transferrin by prior incubation with doubly labeled transferrin were measured in four experiments similar to that shown in Fig 3. In all cases, the rate of transferrin exocytosis was as fast from the Belgrade and iron-deficient reticulocytes as from the control cells. However, in confirmation of earlier observations,^{4,6} the Belgrade reticulocytes released relatively more of their radioiron than did the control reticulocytes. This was not a simple consequence of iron deficiency since it was not observed with the iron-deficient cells.

Table 3. Effects of PMA and Hemin on Iron Uptake and Transferrin Endocytosis by Belgrade, Iron-Deficient, and Control Reticulocytes

Reticulocytes	Treatment	Iron Uptake (Atoms/Cell/ min $\times 10^{-4}$)	Transferrin Endocytosis (Molecules/Cell/ min $\times 10^{-4}$)	Iron: Transferrin
Belgrade	Control	0.60	1.05	0.57
	PMA	0.60	1.25	0.48
Iron-deficient	Control	2.12	1.14	1.86
	PMA	2.50	1.38	1.81
Control	Control	4.87	2.45	1.99
	PMA	5.69	2.97	1.92
Belgrade	Control	0.85	0.78	1.07
	Hemin	0.77	0.42	1.81
Iron-deficient	Control	2.40	1.14	2.10
	Hemin	1.16	0.63	1.84
Control	Control	4.86	2.53	1.92
	Hemin	1.25	0.66	1.88

Reticulocytes were preincubated with PMA (10^{-8} mol/L) or hemin (4×10^{-5} mol/L) for 15 minutes at 37°C prior to the addition of labeled transferrin. Results are from two separate experiments.

Fig 3. Release of intracellular ^{59}Fe and ^{125}I -transferrin (B) from control (●), iron-deficient (○), and Belgrade (▲) reticulocytes. The cells were labeled by incubation with $5 \mu\text{mol/L}$ of diferric ^{59}Fe - ^{125}I -transferrin for 20 minutes at 37°C . After being washed, they were reincubated in the presence of 10 mol/L of unlabeled diferric transferrin, and the loss of intracellular ^{59}Fe and ^{125}I -transferrin was measured by the Pronase method. Results are expressed as percentage of label at the commencement of reincubation. The reticulocyte counts were 45%, 35%, and 26% for the control, iron-deficient, and Belgrade cells, respectively.

Iron release from transferrin. The above experiments showed that the rate of iron accumulation by Belgrade reticulocytes is less than one-half that which would be expected from the rate of endocytosis of transferrin and that a significant proportion of the iron taken up by these cells is later returned to the extracellular medium. These results suggested that the Belgrade reticulocytes were defective in releasing iron from transferrin within the endocytotic vesicles or that the iron after its release was unable to pass through the lining membranes of the vesicles into the cell cytosol. Two types of experiments were used to distinguish these possibilities. The first was based on the observation that certain ferrous iron chelators such as 2,2'-bipyridine are able to chelate iron after it has been released from transferrin by the action of reticulocytes and to transport it from the cells, thus preventing its accumulation by the cells.¹⁸ The chelator-bound and transferrin-bound iron can be distinguished by treatment with ice-cold ethanol, which precipitates transferrin-iron quantitatively but does not precipitate bipyridine-iron.¹⁹ The second approach was to perform cold-chase experiments with rabbit rather than rat transferrin so that radioiron that has been released from ^{59}Fe -labeled rat transferrin and bound by the rabbit protein can be distinguished by precipitation of the rabbit protein with a specific anti-rabbit transferrin antiserum. A similar procedure has been used for other purposes with human and rabbit transferrin and rabbit reticulocytes.²⁰

When control and iron-deficient reticulocytes were incubated with ^{59}Fe - ^{125}I -rat transferrin in the presence of 2,2'-bipyridine, the radioactive iron was transferred to bipyridine at almost the same rate as it was accumulated by reticulocytes in the absence of bipyridine (Fig 4). However, with Belgrade reticulocytes, the rate of transfer of ^{59}Fe to bipyridine was 2.7 ± 0.25 times as fast as iron accumulation by control cells (mean $\pm$ SEM of eight measurements). No transfer to bipyridine occurred in the absence of cells, and with all cell types the transfer was inhibited by NH_4Cl (15

Fig 4. Transfer of iron 2,2'-bipyridine (A) and iron uptake (B) by control (●), iron-deficient (○), and Belgrade reticulocytes (▲). The cells were incubated with 5 $\mu\text{mol/L}$ of diferric ^{59}Fe - ^{125}I -transferrin in the presence (A) or absence (B) of 1 mmol/L of 2,2'-bipyridine. Iron transfer to bipyridine was measured by precipitation of transferrin-bound ^{59}Fe in the incubation solution with ethanol, and iron uptake by the cells was measured after washing as described in the text. The reticulocyte counts were 36%, 26%, and 25% for the control, iron-deficient, and Belgrade cells, respectively.

mmol/L), nigericin (10 $\mu\text{mol/L}$), monensin (10 $\mu\text{mol/L}$) and *N*-ethylmaleimide (2 mmol/L), which also inhibited iron uptake by cells incubated without bipyridine.

The results of one cold-chase experiment with rabbit transferrin are shown in Fig 5. Similar results were obtained in a second such experiment. The fraction of intracellular ^{59}Fe released from the cells during 5-minute cold chase with rabbit transferrin varied with the duration of the period used to label the cells with radiolabeled transferrin. It was low with both control and iron-deficient reticulocytes but high with Belgrade reticulocytes. The values obtained with the first two types of cells changed from 8% to 1% as the uptake time was increased from 1 to 16 minutes. However, with Belgrade reticulocytes, 50% to 54% of the radioiron taken up during 1 to 4 minutes was released and 24% of that was taken up during 16 minutes. Of this ^{59}Fe , 74% to 77% was present on the chase rabbit transferrin, indicating that it had been released from its initial complex with rat transferrin during the intracellular cycle. A control experiment was performed by incubating 1, 2, 5 and 10 μg ^{59}Fe - ^{125}I -labeled rat transferrin with 1 mL of 2.5 mol/L of 50% iron-saturated rabbit transferrin for 10 minutes at 37°C followed by precipitation of the rabbit transferrin with specific antiserum under the conditions used in the above experiments. Only 0.8% to 1.6% of the ^{59}Fe was precipitated by the antiserum. Hence, the results of these experiments confirm the conclusions from the bipyridine experiments that Belgrade reticulocytes are unimpaired in their ability to release iron from transferrin.

DISCUSSION

The results of these experiments demonstrate that the basic defect of iron metabolism inherent in the Belgrade reticulocytes is an impairment of iron transfer into the cells

Fig 5. Effect of time of preincubation with diferric ^{59}Fe - ^{125}I -transferrin on the release of intracellular ^{59}Fe from control, iron-deficient, and Belgrade reticulocytes. The cells were incubated for the indicated times at 37°C with 2.5 $\mu\text{mol/L}$ of ^{59}Fe - ^{125}I -transferrin, washed, treated with 1% Pronase at 4°C to remove surface-bound transferrin, rewashed, and then reincubated with 2.5 $\mu\text{mol/L}$ of 50% iron-saturated nonradioactive rabbit transferrin for 10 minutes at 37°C. Cells and supernatant were separated by centrifugation, 1.5 mg nonradioactive diferric transferrin was added, and the rabbit transferrin was precipitated from the supernatant with goat anti-rabbit transferrin serum. The total height of each column indicates the amount of ^{59}Fe released from the cells and the dark portion of the columns indicates the amount precipitated with the anti-rabbit transferrin serum. Less than 3% of the ^{125}I -rat transferrin released from the cells was precipitated by the antiserum.

after it has been released from transferrin. Iron release from transferrin occurs within endocytotic vesicles.^{7,21} Hence, the site of impaired transfer can be concluded to be the lining membrane of these vesicles. The membrane may contain a carrier for iron that is defective as a consequence of the genetic abnormality expressed in homozygous (b/b) Belgrade rats. Because evidence shows that the iron of transferrin is reduced to the ferrous state within the endocytotic vesicles²² the form of iron transported by the carrier may be Fe^{II} .

Unimpaired endocytosis of transferrin associated with diminished iron uptake and increased iron release from Belgrade cells indicates that the abnormality lies in the metabolism of transferrin-iron after its endocytosis. Although the mechanism of action of bipyridine on iron uptake by reticulocytes is uncertain, considerable evidence shows that it acts after iron has been released from transferrin by the cells.^{18,19} Hence, the results from the experiments with 2,2'-bipyridine and the cold chase with rabbit transferrin clearly show that the amount of iron released from transferrin during its endocytotic cycle in Belgrade reticulocytes is far in excess of that which becomes fixed by the cells. Indeed, the amount released is equivalent to that which can be accounted for by the measured rate of transferrin endocytosis. Also, this release is inhibited by the lysosomotropic agent NH_4Cl and the proton ionophores nigericin and monensin, indicating that the release process is as dependent on acidification of the endocytotic vesicles as it is in normal reticulocytes.²¹ Hence, there is no evidence for a

decreased capacity of Belgrade reticulocytes to release iron from transferrin.

The results of the experiments with PMA and hemin are compatible with the above conclusions and explain why hemin has little effect on iron uptake by Belgrade reticulocytes.²³ As previously reported,¹⁶ PMA stimulated transferrin endocytosis and iron uptake by control and iron-deficient reticulocytes but had no effect on iron uptake by Belgrade reticulocytes even though the rate of endocytosis was accelerated in these cells. Presumably, the defect in membrane transport of iron prevented the cellular uptake of the increased amount of iron being endocytosed with the transferrin. In contrast, hemin inhibits the rate of transferrin endocytosis and recycling.¹⁷ Because these processes are the rate-limiting steps in iron uptake by normal and iron-deficient reticulocytes, there is a proportionate reduction in iron uptake. However, with the Belgrade reticulocytes, the rate-limiting step is the membrane transfer of iron. Therefore, reduced rate of delivery of iron to the site of this transfer by endocytosis would have little effect on the rate of iron uptake until the delivery became rate limiting.

This investigation confirms and extends an earlier report that iron-deficient rat reticulocytes show several alterations in iron metabolism when compared with iron-replete reticulocytes,²⁴ and demonstrates that similar changes occur whether the iron-deficient cells are the result of a genetic defect or are due to iron depletion produced by dietary means combined with bleeding. Thus, total transferrin receptor numbers were lower, but a greater proportion of the receptors were on the outer cell membrane in iron-deficient than in normal reticulocytes. This was accompanied by a diminished rate of iron uptake and impaired incorporation of iron into heme.

Whether the control reticulocytes used in the present work were normal cells is debatable. Because they were collected 7 days after the injection of phenylhydrazine, it is unlikely that they were directly affected by the drug. This is supported by

the observations that their transferrin receptor numbers, distribution, and function were similar to those of iron-replete reticulocytes produced solely by bleeding. However, the control reticulocytes were undoubtedly produced as a consequence of greater erythropoietic stimulation than that received by the iron-deficient and Belgrade cells and hence were probably more immature than the latter cells. This would account for their relatively large size when compared with mature rat erythrocytes and for some of the quantitative differences between the control and other types of reticulocytes. However, the changes in the efficiency of iron incorporation into heme, transferrin receptor distribution, and electrophoretic appearance of cell membrane extracts in the Belgrade and iron-deficient reticulocytes when compared with the control cells are likely to be a consequence of iron deficiency rather than of cell maturity. Such changes were not observed in any samples of control reticulocytes even though reticulocyte count and, presumably, cell maturity varied considerably from one sample to another. The mechanism by which iron deficiency produces the above changes is uncertain but is probably associated in part with the structural changes that lead to their microcytic appearance. The altered electrophoretic properties of the transferrin receptor observed in some electrophoretic runs may be a consequence of altered glycosylation.

The observation that Belgrade reticulocyte ghosts contain a protein absent, or present only in very low concentration, in the membrane of heterozygous, iron-deficient, and control reticulocytes is of particular interest. This may be a result of the genetic defect and directly responsible for the disorder of membrane transport of iron. Future work will be directed at studying the nature and function of this protein.

ACKNOWLEDGMENT

We are indebted to Dr John A. Edwards for providing the breeding stock of Belgrade rats and to Kevin Dufall for the development and care of our Belgrade rat colony.

Analysis With Antiidiotype Antibody of a Patient With Chronic Lymphocytic Leukemia and a Large Cell Lymphoma (Richter's Syndrome)

By L.F. Bertoli, H. Kubagawa, G.V. Borzillo, M. Mayumi, J.T. Prchal, J.F. Kearney, J.R. Durant, and M.D. Cooper

A murine monoclonal antibody made against an idiotypic determinant (Id) of surface IgM/IgD λ molecules on chronic lymphocytic leukemia (CLL) cells of a 71-year-old woman was used for clonal analysis by two-color immunofluorescence. The anti-Id antibody identified IgM⁺/IgD⁺/ λ ⁺ B cells as the predominant cell type of her CLL clone. In addition, substantial proportions of the IgG and IgA B cells and most of the IgM plasma cells in her bone marrow and blood were Id⁺. Six years after diagnosis, the patient died of respiratory failure due to infiltration of lungs by malignant cells. Autopsy revealed a dramatic change in the tumor cell morphology. The lungs, hilar nodes, and liver were infiltrated by a diffuse large cell lymphoma admixed with the

leukemic cells. By immunohistologic staining these anaplastic lymphoma cells were IgM⁺/IgD⁺/ λ ⁺ B cells expressing the same Id noted earlier on the CLL cells. The immunoglobulin gene rearrangement pattern on Southern blot analysis was also the same in leukemic blood cells and in the tissues involved by the lymphoma. Thus, the combination of antiidiotype and immunoglobulin gene analyses in this patient with Richter's syndrome revealed that a CLL clone, seemingly "frozen" in differentiation, was actually undergoing isotype switching, differentiation into plasma cells, and evolution into a rapidly growing and fatal lymphoma.

© 1987 by Grune & Stratton, Inc.

PATIENTS with B cell chronic lymphocytic leukemia (CLL) are at risk for the development of polymorphous leukemias, acute lymphoblastic leukemia, or large cell diffuse lymphoma.¹⁻¹⁶ Richter, who described the latter syndrome in 1928, wondered if the lymphoma was related to or independent of the leukemia, noting that the histology of the two lesions did not give "any indication that they are genetically related."¹ Later investigations of Richter's syndrome compared the isotypes of the immunoglobulin (Ig) expressed by the B cells of the lymphoma and the CLL in Richter's syndrome.^{5,6,10,13-16} Often, the two cell types expressed the same Ig isotypes, an event that could have been due to chance alone. Sometimes the heavy chain isotypes differed, an observation that could be explained either by development of a second neoplastic clone or by isotype switching within a single neoplastic clone, as has been observed in multiple myeloma.¹⁷⁻²⁰ Patients with Richter's syndrome in whom the lymphoma and leukemia expressed different light chains^{6,16} can be most easily explained as two independent malignancies.

More reliable clonal markers exist in the variable (V) domains of the Ig molecule and the gene segments that encode them. During the differentiation of pre-B cells, genes of the heavy and then light chain V regions undergo sequential rearrangements that will endow their progeny B cells with distinctive V_H and V_L regions that serve as antigen receptors.²¹ As a result, a clone of malignant B cells has a characteristic rearrangement pattern of Ig genes that can be revealed by Southern blot analysis and unique idiotypic determinants (Id) in the V_H and V_L domains that can be identified by antiidiotype antibodies. These two approaches to clonal analysis of B cell malignancies complement each other. The Southern blot analyzes populations of cells whereas the anti-Id antibody identifies individual cells belonging to the malignant clone, thereby allowing a precise assessment of their morphologic appearance and coexpression of other determinants. Anti-Id reagents have been used to study the cellular origins and differentiation of various types of human B cell malignancies²²⁻²⁸ but use of such antibodies to analyze Richter's syndrome has not been reported. Southern blot analysis in one patient with Richter's syndrome disclosed that the lymphoma represented the emergence of a clone apparently unrelated to the CLL.¹⁶

The current study is the first report of clonal analysis of a patient with Richter's syndrome using an antiidiotype antibody and Ig gene probes. We used these highly specific probes to define the types of cells comprising the CLL clone and the relationship between the CLL and an emerging large-cell lymphoma.

MATERIALS AND METHODS

Patient G.B. G.B., a 71-year-old woman, developed CLL in 1976. Treatment with chlorambucil and prednisone was initially effective, but by January 1982, the disease was refractory and chemotherapy was stopped. By August 1982, she had developed low-grade fever, night sweats, shortness of breath, progressive enlargement of lymph nodes, spleen, and liver, and bilateral pulmonary infiltrates causing respiratory failure. Transbronchial biopsy revealed infiltration of the lung by CLL cells and a few larger blastic cells. Her WBC count at the time of immunofluorescence analysis was 340,000/ μ L (93% lymphocytes, 6% neutrophils, 1% blast), hemoglobin 9.6 mg/dL, hematocrit 27%, platelet count 120,000/ μ L, serum IgM 46 mg/dL, IgG 740 mg/dL, and IgA 122 mg/dL. Serum protein electrophoresis did not reveal a paraprotein, but a very small abnormal arc of free λ chains was observed on immunoelectrophoresis of serum and urine samples. Despite an advanced stage of disease, treatment with 926 mg of mouse monoclonal anti-Id antibody

markedly reduced the tumor burden in the spleen and circulation and, to a lesser extent, in the lungs. Ventilation was improved transiently, but the patient died of respiratory failure after a month of treatment. Patient G.B. and her family gave informed consent to participate in this study, which was approved by the Institutional Review Board of the University of Alabama at Birmingham Hospitals.

Monoclonal anti-Id antibody. The anti-Id antibody was prepared as previously described.²⁶ In brief, peripheral blood mononuclear cells (MNCs) from patient G.B., most of which were IgM/IgD λ leukemic B cells, were injected subcutaneously at 3-day intervals in BALB/c mice. Hybrids resulting from the fusion of regional lymph node cells with the mouse variant myeloma cell line P3x63-Ag8.653²⁹ were screened for their antibody specificities by an enzyme-linked immunosorbent assay (ELISA) using a panel of myeloma proteins including the homologous IgM λ .²⁶ The latter IgM λ was derived from somatic heterohybrids (GB-Ag) between the patient's leukemic cells and the mouse myeloma cell line; these were constructed as previously described.²⁶ Hybridomas that produced antibodies that reacted with the homologous Ig, but not with other representative myelomas of the same heavy and light chain isotype, were selected and recloned by limiting dilution. One of the clones with anti-Id specificity, GB.8.1, was injected into pristane-primed BALB/c mice to induce ascitic fluid. After dialysis, hybridoma antibody in mouse ascites was purified by diethylaminoethanol (DEAE)-Sephacel ion-exchange column chromatography (Pharmacia Fine Chemicals AB, Uppsala, Sweden) using a continuous ionic gradient (10 mmol/L of Tris-HCl buffer, pH 8.0, to 0.3 mol/L of NaCl-10 mmol/L of Tris HCl buffer, pH 8.0).

Immunofluorescent analysis of cells. Mononuclear cells were isolated from heparinized blood and bone marrow aspirates by Ficoll-Hypaque density-gradient centrifugation. After incubation for 30 to 60 minutes at 37°C to remove cytophilic Ig, nonadherent cells were examined by immunofluorescence.^{26,30} Two-color immunofluorescence was used to examine viable B cells for cell-surface Id and Ig isotype at 4°C in the presence of 0.2% NaN₃, and to stain simultaneously fixed plasma cells for cytoplasmic Id and Ig isotype. This was done using: (a) mouse monoclonal GB.8.1 anti-Id antibody (purified by ion-exchange chromatography); (b) rhodamine-labeled, affinity-purified goat antibody to mouse Ig as a second reagent (this was preabsorbed to remove antibodies cross reactive with human Ig); (c) fluorescein-labeled, affinity-purified goat antibodies to human Ig isotypes as counterstaining reagents (preabsorbed to remove cross-reactivity with mouse Ig).^{26,30} Commercially available antibodies against T cells (Leu 1-5, Becton Dickinson Monoclonal Center, Mountain View, CA), myelomonocytic cells (MMA³¹), natural killer cells (HNK-1³²), B cells (HB-2³³), common acute lymphoblastic leukemia antigen (J5) and HLA-DR antigen (Becton Dickinson Monoclonal Center) were also used.

Immunohistologic analysis of tissues. Tissues obtained at autopsy and fixed in absolute ethanol were embedded in low-melting-point paraffin. Sections were incubated in 10% H₂O₂ in methanol to quench endogenous peroxidase, in 1% bovine serum albumin (BSA) to block nonspecific binding and in phosphate-buffered saline (PBS) for washing. Sections were stained with mouse monoclonal anti-human μ , δ , λ , κ , or GB.8.1 anti-Id followed by biotin-labeled, goat-anti-mouse Ig (preabsorbed to remove antibodies cross-reactive with human Ig) (Southern Biotechnology Associates, Birmingham, AL) and avidin-biotin-horseradish peroxidase complexes (Vector Laboratories, Burlingame, CA). Color was developed with diaminobenzidine, and cells were counterstained with hematoxylin.

Southern blot analysis of peripheral blood and tissues. DNA was extracted³⁴ from blood MNCs frozen at -135°C and from minced tissues that had been obtained at autopsy and fixed in

absolute ethanol. Approximately 10 μ g of DNA from each sample was digested to completion with *Bam*HI (Bethesda Research Laboratories, Gaithersburg, MD) and electrophoresed at 2 V/cm for 60 hours in an International Biotechnologies, Inc. (New Haven, CT) model HRH gel apparatus. The separated DNA fragments were blotted to Zetabind membranes as recommended by the manufacturer (AMF, Meriden, CT). Hybridizations were performed according to Zetabind specifications using J_H 3.2, a 3.2-kilobase (kb) *Bgl*II insert spanning the human J_H exons.³⁵

RESULTS

Specificity of monoclonal anti-Id (GB) antibody. The GB.8.1, a γ 1 κ antibody, proved specific for an Id of the IgM λ molecules expressed by the leukemia cells of patient G.B., as determined by ELISA and immunofluorescence assays. By ELISA, the GB.8.1 antibody reacted with the IgM λ secreted by somatic heterohybrids of the patient's tumor cells and not with a panel of 10 human myeloma proteins and normal IgG. When the somatic heterohybrid cells were stained with anti-Id, anti- μ or anti- λ antibodies, ~60% and ~20% of the cells were μ^+ and λ^+ , respectively. All λ^+ cells coexpressed μ chains. The frequency of Id⁺ cells paralleled that of cells expressing both μ heavy and λ light chains, suggesting that the GB.8.1 anti-Id did not recognize the idiotypic determinants on free μ heavy chains.

The GB.8.1 antibody was found to react with ~1% of B cells and plasma cells from normal individuals, a result that is in agreement with the previous findings in our laboratory and by others.^{25,26,36,37} The GB.8.1 anti-Id antibody stained normal IgM, IgG, and IgA plasma cells with similar frequencies. However, its reactivity was restricted to plasma cells expressing λ light chains, indicating a λ -dependent idiotype.

Expression of surface markers, Ig isotypes, and GB.8.1 idiotype by blood and bone marrow MNCs from patient G.B. Analysis of the phenotype of blood MNCs (without depletion of adherent cells) obtained from patient G.B. before immunotherapy revealed that ~80% expressed the B cell antigen (HB-2), HLA-DR, and the Leu-1 antigen, but < 0.5% were common acute lymphoblastic leukemia antigen (CALLA) positive. The frequencies of T cells and macrophage/monocytes identified by the Leu-4 and MMA antibodies were only 2%, but their absolute numbers in her blood were twofold to fourfold higher than normal values. An inverted ratio of helper T cells (Leu-3⁺, 0.8%) to suppressor or cytotoxic T cells (Leu-2⁺, 1.8%) was also noted. Granular lymphocytes reactive with the HNK-1 antibody were not observed in her blood.

To examine the leukemic cells from G.B. for the expression of Ig isotypes and the GB.8.1 idiotype, two-color immunofluorescence analysis was performed on both blood and bone marrow samples. Eighty percent to 95% of the bone marrow and blood MNCs expressed IgM, IgD and λ determinants on their cell surface (Table 1). Almost all IgM⁺/IgD⁺ cells expressed the GB.8.1 Id, indicating a monoclonal cell origin. Moreover, mature plasma cells expressing IgM λ and GB.8.1 idiotype were demonstrated in both blood and bone marrow samples, suggesting differentiation of some members of the leukemic B cells into IgM λ plasma cells.

Table 1. Two-Color Immunofluorescence Analysis of Ig Isotype and Idiotype Expression by the MNCs of Patient G.B.

Cell Phenotype	Blood		Bone Marrow	
	% MNC (%Id ⁺)		% MNC (%Id ⁺)	
Pre-B				
sig ⁻ cμ ⁺	< 0.05		< 0.05	
B cells				
sigM	97	(> 99)	80	(> 99)
sigD	95	(> 99)	80	(> 99)
sigG	0.05	(77)	NT	
sigA	0.03	(38)	NT	
sκ	< 0.05	(< 10)	NT	
sλ	91	(> 99)	NT	
Plasma cells				
cIgM	0.07	(> 99)	0.05	(87)
cIgG	< 0.05		0.05	(3)
cIgA	< 0.05		< 0.05	(10)
cκ	< 0.05		NT	
cλ	0.05	(> 99)	0.10	(86)

WBC count was 340,000/μL (93% lymphocytes). Eighty-six IgG⁺, 40 IgM⁺, and 40 IgA⁺ bone marrow plasma cells were counted, and 48 IgG and 50 IgA blood B cells were counted.

Abbreviations: s, surface; c, cytoplasmic; NT, not tested.

Circulating B cells expressing other Ig isotypes were extremely low in relative frequencies, but normal or slightly high in absolute numbers. High proportions of both IgG and IgA B cells expressed the GB.8.1 idiotype. Evidence for non-IgM/IgD members of the leukemic clone was also obtained from the idiotypic analysis of marrow plasma cells. A similar distribution of GB.8.1 idiotype among B cells and plasma cells was also observed in the patient's blood 1 year earlier (data not shown). Cells of pre-B phenotype were very infrequent in her marrow and blood samples.

Tumor morphology and distribution at autopsy. After a 30-day course of anti-Id therapy, G.B. died of respiratory failure. The autopsy, performed 3 hours after death, revealed extensive leukemic infiltration of bone marrow, lymph nodes (hilar and retroperitoneal), spleen (950 g), liver (3,000 g), lungs (right 1,350 g; left 1,050 g) and other organs (pancreas, adrenal glands, kidneys, urinary bladder, brain). In addition, hilar lymph nodes, large areas of the lungs, and the hepatic portal triads were diffusely infiltrated by large pleomorphic cells in which the cytoplasm was pale and moderately abundant. The nuclei were often multiple and angular, and the nucleoli were prominent. These large cells were morphologically distinct from the admixed CLL cells, resembling the large cell lymphoma described by Richter in CLL, in which many cells were anaplastic and multinucleated.¹ There were also histologic features of adult respiratory distress syndrome with extensive alveolar hemorrhage and acute renal tubular necrosis.

Expression of Ig isotype and GB.8.1 idiotype by large cell lymphoma. Ethanol fixed sections of the spleen, liver, lungs, and hilar lymph nodes were examined immunohistologically for expression of immunoglobulin determinants (Fig 1). The large, anaplastic lymphoma cells expressed abundant IgM, λ light chains and the GB.8.1 idiotype in their cytoplasm. They did not express IgD, and staining with anti-human κ was negative. Intact membrane immunoglobu-

lin determinants on the small CLL cells were below the threshold of detection in the paraffin-embedded tissues, but immunofluorescence examination of frozen sections of spleen, lymph nodes, and liver showed the CLL cells to be IgM⁺/IgD⁺/λ⁺ and Id⁺.

Southern blot analysis of peripheral blood and tissues. The DNA isolated from peripheral blood, in which 97% of the cells were CLL cells, and from the spleen, which was extensively infiltrated by the CLL, was found in both cases to have two prominent J_H segment rearrangements (Fig 2). In the DNA from lung and liver, which were infiltrated by both the CLL and the large cell lymphoma but in which infiltration by malignant cells was less extensive, the J_H segment was predominantly in germline configuration, but fainter bands were visible that corresponded to the rearrangements observed in the blood and spleen samples.

DISCUSSION

These studies of a patient (G.B.) with CLL, who later developed a large cell lymphoma, provided results that are of interest from several viewpoints. First, although the predominant leukemic cell was an IgM/IgDλ B cell, Id⁺ members of the malignant clone also included IgG and IgA B cells that did not exhibit neoplastic growth characteristics. Small subpopulations of B cells expressing heavy chain isotypes different from the isotype of the predominant malignant cells have also been observed in multiple myeloma, Waldenström's macroglobulinemia, and acute B cell leukemia.^{25-26,28} Similarly, patients have been described with multiple myeloma producing two paraproteins that express the same variable regions but different heavy chain isotypes.¹⁷⁻²⁰ These data suggest that these malignant clones include a preneoplastic precursor cell capable of isotype switching.

IgM plasma cell members of the malignant clone far outnumbered the normal Id⁻ IgM plasma cells, and Id⁺ IgG and IgA plasma cells were present in much lower numbers. These results indicate that differentiation into mature plasma cells was occurring in the leukemic clone although most of the neoplastic cells appeared to have been arrested at the B lymphocyte level. This phenomenon has been observed in an occasional CLL patient with prominent paraprotein derived from plasma cells belonging to the neoplastic clone.³⁸ G.B. did not have such an obvious paraprotein but, using the monoclonal anti-Id antibody in an inhibition radioimmunoassay, circulating Id⁺ immunoglobulin could be demonstrated in a serum concentration of 380 μg/mL (data not shown). Patients with CLL often have a small amount of monoclonal protein in their sera.^{39,40} Together, these data suggest that differentiation to plasma cells by some members of CLL B cell clones is common.

Autopsy revealed that the lungs, hilar lymph nodes, and liver were infiltrated by two populations of tumor cells dramatically different from each other in morphology. One population was constituted by small CLL cells and the other by large anaplastic cells with the histologic appearance of a diffuse large cell lymphoma. Both cell types expressed the same GB.8.1 idiotype. Thus, in this case of Richter's syndrome, the rapidly growing lymphoma must have evolved from the more indolent leukemia. The results of the Southern

Fig 2. Southern blot analysis of peripheral blood, spleen, and liver cells of patient G.B. Top, restriction enzyme map of a 16.5-kb region spanning the human germline J_H - C_μ region. The J_H probe is a 3.2-kb *Bgl*II (*Bg*) fragment; *B*, *Bam*HI; *H*, *Hind*III. DNA from the tissue samples was digested with *Bam*HI, electrophoresed, blotted, and analyzed with the J_H probe. The blood, spleen, and liver samples contain the same J_H rearrangements (arrowheads), suggesting infiltration of these tissues by a single B cell clone. The same two J_H rearrangements were also found in DNA from lung tissue (data not shown).

blot analysis are consistent with this conclusion because the DNA from tissues infiltrated by both lymphoma and leukemia carried the same J_H rearrangements as the DNA from blood cells in which only the leukemic cells were present. This mutation probably occurred spontaneously or as a result of alkylator therapy before the anti-Id was given, but we

cannot exclude the possibility that growth of the lymphoma accelerated during anti-Id therapy. The lymphoma cells expressed the GB IgM λ but not the IgD λ , and many of them expressed relatively abundant cytoplasmic Ig. Loss of IgD occurs when mature B cells are activated by antigen and growth factors and undergo differentiation to express greater amounts of cytoplasmic Ig.⁴¹ The transformation of the leukemic B cells into anaplastic lymphoma cells may thus mimic the normal pathway of B cell development.

In patients with low-grade B cell lymphomas, the development of high-grade lymphomas has been caused either by a new malignancy or by evolution of the older malignancy.⁴² Potentially, bclonal B cell lymphomas could arise from a common malignant B cell precursor.⁴³ High-grade lymphomas occur more rarely in CLL than in the low-grade lymphomas, and it is not known which mechanism is the more common cause of Richter's syndrome. In one patient, a CLL clone transformed into an acute lymphoblastic leukemia (ALL) expressing Ig with the same antigen binding specificity.² Development of a second independent B cell malignancy has been described in two patients with Richter's syndrome.^{6,16} Richter's syndrome occurring within the same B cell clone has been well documented only in the case of G.B.

Anti-Id antibodies, by providing a precise means of identifying individual cell members of a neoplastic clone, may thus reveal a dynamic picture of a CLL clone undergoing isotype switching, differentiation, and multiple transformational events.

ACKNOWLEDGMENT

We thank Frances Bondy and Renata Marshall for their generous support, Dr G. Larry Gartland for FACS analysis, Dr Jack Sloyer for endotoxin assay, Dr Jack C. Geer for postmortem examination, Dr Kazuo Komiyama for help in immunohistologic staining, Dr Scott Freeman and Sara B. Tarrt for technical assistance, and E. Ann Brookshire and Tami Rhinehart for preparation of the manuscript.

Clinical Significance of Low Levels of Myeloperoxidase Positivity in Childhood Acute Nonlymphoblastic Leukemia

By Ching-Hon Pui, Frederick G. Behm, David K. Kalwinsky, Sharon B. Murphy, Debra L. Butler, Gary V. Dahl, and Joseph Mirro

The clinical significance of a low percentage of myeloperoxidase-positive blast cells in childhood acute nonlymphoblastic leukemia was determined. Of 155 consecutive cases studied by cytochemical staining methods, 14 were characterized by 4% to 15% (median 6%) myeloperoxidase-positive blasts. All 14 cases showed reactivity to Sudan black B stain, and 7 had Auer rods. The morphological subtypes of leukemia were M1 (8 cases), M2 (3), M4 (1), and M5 (2). Immunological marker studies disclosed the lymphoid-associated T11 antigen on cells from 8 of the 11 cases tested. Other lymphoid-related findings in these 8

cases included the T3 antigen and E rosette formation in 1 case each. Among cases that were prospectively studied for the expression of lymphoid-associated markers, 6 of 8 with low levels of myeloperoxidase positivity compared with only 1 of 44 with higher levels ($>15\%$) possessed such features ($P < 0.001$). We conclude that low levels of myeloperoxidase reactivity distinguish cases of acute leukemia in which the blast cells coexpress lymphoid (T11 antigen) and myeloid markers.

© 1987 by Grune & Stratton, Inc.

CLASSIFICATION of the acute leukemias by the French-American-British (FAB) system requires analysis of the cytochemical features of the malignant blast cells.¹ Although reactivity to Sudan black B (SBB) stain can no longer be considered a lineage-specific marker,² myeloperoxidase (MPO) positivity is still regarded to be diagnostic of acute nonlymphoblastic leukemia (ANLL). Investigators in the FAB cooperative group selected $\geq 3\%$ MPO positivity as a criterion for the diagnosis of ANLL.¹ Although the percentage of blasts containing MPO activity ranges widely, from 3% to 100%, most cases of myelocytic, promyelocytic, or myelomonocytic leukemia are characterized by high levels of the enzyme. Whether cases with marginal MPO positivity are sufficiently different from more typical cases to warrant reclassification has not been established. The results reported here indicate that low levels of blast cell MPO activity distinguish a subgroup of children with ANLL whose blasts are more likely to express lymphoid-associated antigens.

MATERIALS AND METHODS

Patients. From April 1980 to April 1986, 155 consecutive children with newly diagnosed ANLL were enrolled in two successive clinical trials at St Jude Children's Research Hospital.^{3,4} Informed consent was obtained for all patients, and the investigations were approved by the institution's clinical trials committee.

Morphological and cytochemical studies. Bone marrow smears were stained by standard techniques, including Wright's-Giemsa, MPO, SBB, periodic acid-Schiff reagent (PAS), naphthol AS-D chloroacetate esterase (CAE) and α -naphthyl butyrate esterase (ANB).⁵ Blast cell morphology was classified according to FAB criteria.¹ By convention, cytochemical staining was considered positive if $>3\%$ of the blasts reacted. Blast cell MPO positivity, based on analysis of 200 cells per sample, was reviewed and confirmed independently by two of us (F.G.B. and D.L.B.). There was good agreement of results between the two readers, with differences generally $<2\%$. In no instance did the discrepancy lead to a different interpretation of MPO positivity.

Immunophenotyping. Leukemic blast cells from marrow aspirates were separated on a density gradient, and only samples containing $>85\%$ blasts were assayed. They were studied for spontaneous rosette formation with use of sheep erythrocytes incubated at 37°C . Cell-surface antigens were detected with a standard indirect immunofluorescence assay using monoclonal antibodies representative of the cluster of differentiation (CD) groups identified at the

First and Second International Workshops on Human Leukocyte Differentiation Antigens. The monoclonal antibodies to myeloid-associated antigens included anti-My-1 (X-Hapten, CD-15),⁶ MCS.1,⁷ MCS.2 (CDw-13, 150),⁸ Mol (CD-11),⁹ and SJ-D1 (CDw-13, 150).¹⁰ The blasts were also tested with monoclonal antibodies to lymphoid-associated antigens, including J5 (common acute lymphoblastic leukemia antigen, CALLA, CD-10),¹¹ T11 (CD-2),¹² T101 (CD-5),¹³ and T3 (CD-3).¹⁴ Two observers independently counted 200 cells in each assay; the results were judged positive if $\geq 40\%$ of the blast cells had surface fluorescence. Terminal deoxynucleotidyl transferase (TdT) was detected by an indirect immunofluorescence assay.¹⁵

RESULTS

MPO activity was demonstrated in 3% to 100% of the blast cells from 37 of 43 cases with an M1 FAB type, 47 of 47 with M2, 9 of 9 with M3, 29 of 29 with M4, and 4 of 25 with M5. The diagnosis of ANLL in the six M1 cases with negative MPO reactivity was based on the presence of Auer rods, ultrastructural myeloperoxidase or myeloid markers as defined by monoclonal antibodies; none of them expressed any lymphoid markers. The two cases of M7 leukemia lacked evidence of the enzyme. Of the 126 cases that showed MPO activity, 14 were characterized by 4% to 15% (median 6%) MPO-positive blast cells in bone marrow samples (Table 1);

the remaining cases had >25% blast cells with MPO positivity, most >80%. None of the cases had MPO positivity between 16% and 25%. Blast cells from each of these 14 cases with low levels of MPO positivity met standard FAB criteria for ANLL. All cases were positive for SBB, and seven contained Auer rods. Their FAB designations were M1 in 8 cases, M2 in 3, M4 in 1, and M5 in 2.

Blast cells from 12 of the 14 patients (excluding nos. 8 and 10) were examined for lymphoid- and myeloid-associated differentiation markers. All but three cases (nos. 3, 5, and 6) were defined by reactivity to one or more myeloid-associated monoclonal antibodies (data not shown). Studies with lymphoid-associated monoclonal antibodies, although not disclosing a consistent pattern of binding, indicated unequivocal lymphoid characteristics in eight of the 12 cases tested (nos. 1, 2, 4, 6, 7, and 12-14, Table 1). Evidence of lymphoid involvement consisted of reactivity with antibodies to the T11 (CD-2) antigen in all eight cases, coupled with the expression of T3 (CD-3) or formation of heat-stable E rosettes in one case each. Blast cells from an additional patient (no. 5), which were not tested for T11, were positive for CALLA. TdT activity was detected in all but one of the cases that demonstrated T11 and in two others that were devoid of more definitive lymphoid markers.

The relationship between MPO reactivity and the expression of lymphoid-associated antigens was determined in the 56 consecutive patients who had been prospectively studied for these features since August 1983 and had adequate leukemic cell samples. Among these cases, eight (including cases 1, 3, 4, 6, 7, and 11 through 13) were characterized by 4% to 15% MPO-positive blasts, and the remainder were characterized by negative MPO activity (four cases) or >25% MPO positivity (44 cases). Six of eight cases with low MPO reactivity had blast cells with lymphoid-associated markers, contrasted with only one of those with >25% MPO positivity ($p < 0.001$). The patient with >25% MPO also expressed T11 antigen. None of the four cases with negative MPO activity expressed lymphoid-associated antigens.

The clinical features of patients whose leukemic cells

expressed lymphoid-associated markers did not clearly discriminate between these cases and typical ANLL. Ages ranged from 6 to 18 years (median 14 years), presenting leukocyte counts from 2 to $171 \times 10^9/L$ (median $16.2 \times 10^9/L$), platelet counts from 4 to $312 \times 10^9/L$ (median $120 \times 10^9/L$) and hemoglobin levels from 4.1 to 14 g/dL (median 10.4 g/dL). All patients had lymphadenopathy but only three (nos. 1, 2, and 13) had hepatosplenomegaly. Initial CNS leukemia was evident in patient 4, and patient 2 had an anterior mediastinal mass.

DISCUSSION

Bennett and associates¹ considered 3% as the lower limit for MPO positivity in the FAB system of leukemia cell classification. Results of the present study suggest that a higher level of positivity is required to distinguish "typical" cases of ANLL from those with equivocal features. We demonstrated that a criterion of 4% to 15% MPO positivity yields a high percentage of cases with lymphoid-associated differentiation markers, primarily the T11 antigen. Although identified on normal, activated B cells,¹⁶ T11 has not been detected on normal myeloid cells. Additional evidence of lymphoid involvement was provided by T3 positivity and E rosette formation in one case each. Although TdT activity and/or CALLA were also expressed in some of our cases, these markers can no longer be considered lymphoid-specific markers. TdT activity has been demonstrated in 5% to 10% of ANLL cases that were unequivocally myeloid in origin.¹⁷ CALLA has been identified on renal tubular and glomerular cells, granulocytes, fibroblasts, fetal small intestine epithelial cells, mammary epithelium, and myeloma cell lines (see ref. 18 for review). Nonetheless, we think it noteworthy that the majority of our cases with low MPO positivity expressed TdT activity, a far greater proportion than has been reported in ANLL.

The immunologic marker findings in cases with low MPO activity are most compatible with the newly recognized entity of acute mixed-lineage leukemia, in which the leukemic cells coexpress markers generally thought to be

restricted to a single lineage.¹⁹⁻²³ None of the cases in this study had cytogenetic evidence for biclonal disease, whereas evidence for simultaneous expression of lymphoid and myeloid markers was found in all four cases tested (data not shown). The diagnosis of acute mixed-lineage leukemia is best exemplified by case 2. The presence of an anterior mediastinal mass and the expression of T11 and T3 antigens in 83% and 87% of this child's blast cells would be considered by most investigators as diagnostic of T cell acute lymphoblastic leukemia. However, there was also strong evidence for myeloid differentiation, including 4% myeloperoxidase positivity, the presence of Auer rods, and the expression of myeloid antigens in blast cells [84% reacted with Mol (CD-11) and 35% with MCS.1 (CDw-15) monoclonal antibodies].

Consistent with our data, the reported patterns of monoclonal antibody binding in cases of acute mixed-lineage leukemia have generally included high percentages of T11 positivity with variable levels of other lymphoid markers.²¹ These leukemias either may arise from multipotential progenitors with capacity of lymphoid or myeloid differentiation^{22,23} or had aberrant gene expression during malignant proliferation.¹⁹ The clinical importance of acute mixed-lineage leukemia lies in the suggestion that such patients may not respond to therapy conventionally prescribed for myeloid leukemia, but require treatment directed to the lymphoid leukemias.²¹

MPO, a major 135,000-dalton protein, is localized to the

azurophil granules in the myeloid series of hematopoietic cells. MPO synthesis has been suggested to occur at the promyelocytic stage of differentiation and ceases as myeloid cells differentiate to myelocytes, metamyelocytes, granulocytes, and macrophages.²⁴ Abundant MPO activity is typical of progranulocytic leukemia; the activity is decreased in myeloid variants of ANLL and low to absent in monocytic subtypes.²⁵ Thus, the lack of lymphoid markers on blast cells in the single case of M5 leukemia that was tested is not surprising. If acute mixed-lineage leukemia originates in a pluripotent stem cell with the ability to differentiate in either the lymphoid or myeloid pathway,^{19,23} and if the developmental stage of such transformed cells is more primitive than is usually seen in cases of ANLL, one might expect to find low MPO activity as a characteristic feature of this form of the disease.

Currently, the diagnosis of acute mixed-lineage leukemia is based on an extensive battery of cytochemical and immunological tests.²¹ We believe that low MPO positivity in cases of ANLL should be regarded as a potential indicator of this clinical entity. Our interpretation assumes additional significance in view of the variability of clinical and laboratory features among such patients.

Recombinant Human TNF α Stimulates Production of Granulocyte Colony-Stimulating Factor

By H. Phillip Koeffler, Judith Gasson, John Ranyard, Larry Souza, Michael Shepard, and Reinhold Munker

Tumor necrosis factor α (TNF α) stimulates production of granulocyte colony-stimulating factor (G-CSF) protein and mRNA in fibroblast cells. In contrast, TNF β is at least 1,000-fold less potent than TNF α in increasing levels of G-CSF and GM-CSF activity and mRNA. The fibroblasts

produce G-CSF and GM-CSF mRNA in a coordinate fashion after exposure to TNF. The ability of TNF α to stimulate production of CSF in fibroblasts may be pivotal to regulation of hematopoiesis.

© 1987 by Grune & Stratton, Inc.

COLONY-STIMULATING FACTORS (CSFs) are required for the survival, proliferation, and differentiation of hematopoietic cells. The granulocyte (G) and granulocyte-monocyte (GM) CSFs stimulate proliferation of committed stem cells for granulocytes and macrophages, and the GM-CSF can also enhance the proliferation of multipotential, erythroid, eosinophil, megakaryocyte, and mast stem cells.¹⁻⁴ Recent studies suggest that these CSFs also play an important role in the function of mature granulocytes, eosinophils, and monocyte/macrophage.^{1,2,5-7}

Various tissues can produce biologically active CSF, suggesting either that many different cell types can produce CSF or, alternatively that one cell type existing in all tissue may be the source of CSF. Early evidence suggested that monocyte-macrophages were capable of releasing CSF⁸; further studies showed that endothelial cells and fibroblasts,¹⁰ activated T lymphocytes,^{11,12} and cultured nonhematopoietic lines^{13,14} can also produce CSF. Little was known of the mechanism that modulated the production of CSF by the mesenchymal cells until Bagby and co-workers made the seminal observation that conditioned medium from monocytes cultured in vitro stimulated both endothelial cells and fibroblasts to synthesize CSF.^{15,16} Further studies showed that interleukin 1 (IL 1)^{16,17} and tumor necrosis factor (TNF)^{18,19} stimulated endothelial cells, normal fibroblasts, smooth muscle cells, and malignant cells of squamous and adenomatous origin to synthesize GM-CSF protein and mRNA. The present study shows that TNF α stimulates production of G-CSF protein and mRNA in fibroblasts. In contrast, TNF β was nearly 1,000-fold less potent than TNF α in the stimulation of CSF accumulation.

MATERIALS AND METHODS

Fibroblast cultures and preparation of conditioned medium. Normal human adult lung fibroblasts (obtained from informed volunteers A.W. and P.T., by pulmonary lavage) and normal human embryonic lung fibroblasts (WI 38, obtained from the American Type Tissue Culture Collection) were cultured in α medium (Flow Laboratories, McLean, VA) supplemented with 10% fetal bovine serum (FBS). The adult lung fibroblasts were cultured for 6 weeks before their use. By this time the cell population contained no macrophages, as shown by the absence of cells staining for nonspecific esterase. In the experiments described, fibroblasts from the fifth to the fifteenth passage were used, and the cell density ranged from 1 to 5 $\times 10^4$ cells/cm². The CSF-Ca1 line was developed from a patient with adenocarcinoma of the lung. Cells were subcultured by brief (1 minute, 37°C) treatment with 0.05% trypsin/0.02% disodium EDTA (wt/vol in phosphate-buffered saline, PBS). The cells were incubated for periods from 12 hr to 4 d with complete α medium supplemented with varying concentrations of recombinant (r) TNF α , TNF β , or IL 1. Supernatants from

fibroblast cells were prepared by centrifuging the cell culture at 1,000 g for 10 minutes. The conditioned medium (CM) was stored at -20°C for up to 4 months without loss of CSF.

Colony formation in soft agar. Cells were plated in Lux culture dishes in a two-layer soft agar system according to previously described methods.^{20,21} The underlayer contained 0.5% agar; the upper layer contained 0.3% agar (Difco Laboratories, Detroit). The culture medium was α medium. For each plating experiment, 2 $\times$ stock solutions of agar were prepared by autoclaving with distilled water, and the agar was kept at 43°C. For each layer, these stock solutions were mixed with prewarmed α medium [which contained a final concentration of 17% fetal calf serum (FCS) and 1% penicillin-streptomycin], and 1 mL was carefully pipetted into each culture dish. This mixture became semisolid at room temperature within 20 minutes. The CSF and the compounds to be tested were mixed into the underlayer before solidification of the agar. For human bone marrow, 2 $\times 10^5$ cells were plated. Cultures were placed in a humidified atmosphere, 5% CO₂ at 37°C. Colonies (≥ 40 cells) were scored after 10 to 12 days with an inverted microscope. All experiments were done using triplicate or quadruplicate plates for each experimental point. Control plates with no CSF were performed for each experiment.

RNA hybridization studies. For cytoplasmic RNA, freshly harvested cells were suspended in hypotonic buffer 10 mmol/L of Tris-HCl pH 7.4, 1 mmol/L of KCl, 3 mmol/L of MgCl₂ and were lysed with Nonidet P-40 (0.3%). Nuclei were removed by centrifugation. Cytoplasmic RNA was extracted by the phenol/chloroform method as essentially described²² and quantified by absorbance at 260 nm. Samples were denatured at 65°C for 10 minutes, size-separated by an agarose formaldehyde gel [1% agarose (Bethesda Research Laboratories, Gaithersburg, MD), 50 mmol/L of Na Acetate, 10 mmol/L of Na₂ EDTA, 200 mmol/L of MOPS, and 2.2

mol/L of formaldehyde] and transferred to a nylon-membrane filter (ICN Biomedicals, Irvine, CA). Filters were dried, baked at 80°C in vacuo for 2 hours and then prehybridized for 16 to 24 hours. Hybridizations with [³²P]-labeled cDNAs (1×10^6 cpm/mL) were performed at 42°C for 16 to 24 hours in a solution containing 50% (vol/vol) formamide, $2 \times$ SSC ($1 \times$ SSC is 300 mmol/L of NaCl, 30 mmol/L of sodium citrate), $5 \times$ Denhardt's ($1 \times$ Denhardt's is 0.02% Ficoll/0.02% polyvinylpyrrolidone/0.02% bovine serum albumin BSA), 0.1% sodium dodecyl sulfate (SDS), 1 mmol/L of EDTA, 10% (vol/vol) dextran sulfate (Sigma) (mol wt 500,000), and 100 µg/mL of salmon sperm DNA (Sigma Chemicals, St Louis). Filters were washed to a stringency of $0.1 \times$ SSC, 1% SDS at 65°C and exposed for 24 to 48 hours at -70°C to Kodak XAR-5 film. The GM-CSF probe was a full-length cDNA²³ that was [³²P]-labeled by nick-translation.²⁴ The G-CSF probe was an oligonucleotide (30 bases) that was end-labeled with [³²P]-γ-ATP.²⁴ The sequence of the oligonucleotide was 5'GGGCTGGGCA-AGGTGGCGTAGAACGCGTA3'. A densitometer was used to scan autoradiograms of the hybridized blots.

Reagents. The TNFα monoclonal antibody was a generous gift of C. Nelson (Genentech). The antibody had a neutralization titer of 6,000 U of TNFα/µg protein. The antibody against GM-CSF is a heterologous rabbit antiserum raised against purified biosynthetic (recombinant, r) GM-CSF; the antibody against G-CSF is a monoclonal antibody raised against rG-CSF. The human TNFα and β and IL 1 were purified to homogeneity and had a specific activity of 3.4×10^7 U/mg, 4×10^7 U/mg, and 3×10^7 U/mg, respectively. With the limulus amoebocyte lysate (LAL) assay, the level of endotoxin detected in the three cytokines was <0.8 ng/mL, which is a level incapable of stimulating GM-CSF mRNA in fibroblasts.

RESULTS

Effect of monokines on CSF synthesis. rTNFα, TNFβ, or IL 1 at various concentrations were added to normal adult lung fibroblasts for 3 days, and the supernatants were harvested and tested for CSF activity using normal human marrow (Fig 1). Both rTNFα and IL 1 stimulated, in parallel, normal human lung fibroblasts in a dose-response fashion to produce increasing amounts of CSF, with 25 and 40 U/mL IL 1 and TNFα, respectively, stimulating 50% maximal levels of CSF. Maximal stimulation by both cytokines occurred at 500 U/mL. In contrast, TNFβ at 5,000 U/mL stimulated fibroblasts only weakly to produce CSF (Fig 1). The highest concentration of IL 1, TNFα, and TNFβ in the supernatants was 500 U/mL. When this concentration was added to soft agar plates containing rGM-CSF (100 pmol/L), IL 1 and TNFβ had no effect, and TNFα inhibited by 20% the clonal growth of GM-CSF in soft agar plates (data not shown).

Experiments were designed to determine how long fibroblasts could synthesize CSF after an initial stimulation with TNFα. The adult lung fibroblasts were incubated with TNFα (300 U/mL) for 72 hours washed, and reincubated for four sequential 24-hour periods in culture medium lacking TNFα (Fig 2). A gradual reduction in CSF release occurred; the cells released 20% of the CSF activity at 72 hours after the TNFα was removed as compared with that produced on the day the TNF was removed from the culture media (Fig 2).

Supernatants from lung fibroblasts cultured for 2 days with TNFα (200 U/mL) were cocultured for 1 hour with a

Fig 1. Stimulation of colony-stimulating factor (CSF) production by human fibroblasts cultured with either recombinant tumor necrosis factors TNFα, TNFβ, or interleukin 1 (IL 1). Monolayers of human adult lung fibroblasts were cultured with 0 to 5,000 U/mL of either TNFα (▲—▲), TNFβ (○—○), or IL 1 (●—●) for 4 days. The conditioned media (10% vol/vol) were added to soft agar dishes containing normal human marrow cells (triplicate dishes per TNF concentration). Colonies of ≥ 40 cells were enumerated on day 12 of culture. Results represent mean $\pm$ SE of three experiments.

Fig 2. Requirement for the presence of tumor necrosis factor (TNF) α for the production of colony-stimulating factor (CSF) by fibroblasts. Adult lung fibroblasts were cultured for 48 hours in TNFα (200 U/mL) and conditioned media (CM) were harvested and assayed for CSF (represents time 0). The fibroblast cells were washed and reincubated in culture media not containing TNFα. CM were harvested completely at 24-hour intervals and assayed for CSF (10% vol/vol of CM in soft gel culture). The mean $\pm$ SE of three experiments with quadruplicate plates at each time point is shown. Data are presented as a percentage of colonies present at time 0 (mean $85 \pm 8 \pm$ SE).

monoclonal antibody directed against human G-CSF and CSF activity was measured. The G-CSF antiserum decreased the CSF activity of the conditioned medium by a mean 41% as compared with preimmune mouse sera (Table 1). Heterologous rabbit antisera raised against purified rGM-CSF decreased CSF activity by 72% as compared with preimmune rabbit sera. Further experiments showed that G-CSF antibody inhibited rG-CSF but not rGM-CSF, and GM-CSF antibody inhibited rGM-CSF but not rG-CSF (Table 1).

As further proof that TNF was the factor that stimulated CSF production, studies were conducted with a monoclonal antibody to TNF. This antibody (vol/vol) blocked the stimulation of fibroblasts to synthesize CSF in a 1-hour preincubation with rTNF (Table 1). To show that the presence of the anti-TNF did not directly affect the colony assay, the same amount of anti-TNF was added together with rGM-CSF to the soft gel assay (Table 1). Anti-TNF had no effect on colony formation. Likewise, anti-TNF had no effect on the production of CSF by the fibroblast monolayers previously stimulated with TNF α (200 U/mL) (data not shown).

Elevated levels of G-CSF mRNA after exposure of fibroblasts to TNF α . Primary adult lung fibroblasts cultured with TNF α (200 U/mL) contained elevated levels of both G-CSF and GM-CSF mRNA (Figs 3A and B). Stimulation occurred within 24 hours of exposure and increased in activity for the next several days. Messenger RNA for GM-CSF but not G-CSF would be identified in human T lymphotropic virus-1 (HTLV-1) infected T lymphocytes

Table 1. CSF Production After Exposure of Lung Fibroblasts to TNF α

Growth Factor	Fibroblasts Cultured With TNF (200 U/mL)	Antibody	Normal Human Myeloid Colony Formation (Mean $\pm$ SE)
CM fibroblasts	0	0	<10
CM fibroblasts	+	0	82 $\pm$ 7
CM fibroblasts	+	G-CSF*	48 $\pm$ 5
CM fibroblasts	+	GM-CSF*	23 $\pm$ 6
rG-CSF (20 ng)	0	0	78 $\pm$ 8
rGM-CSF (100 pmol/L)	0	0	83 $\pm$ 6
rG-CSF (20 ng)	0	G-CSF	<10
rG-CSF (20 ng)	0	GM-CSF	74 $\pm$ 8
rGM-CSF (100 pmol/L)	0	GM-CSF	<10
rGM-CSF (100 pmol/L)	0	G-CSF	79 $\pm$ 7
CM fibroblasts	+	TNF*	<5
rGM-CSF (100 pmol/L)	0	TNF*	79 $\pm$ 7

TNF (200 U/mL) was cultured with adult lung fibroblast cells (5×10^5 /mL) for 3 days in the presence of α medium plus 10% fetal calf serum. CM were collected and tested (10% vol/vol) for their ability to stimulate clonal proliferation of normal human marrow myeloid stem cells. Results represent mean of two experiments with quadruplicate plates.

*The G-CSF monoclonal antibody and the GM-CSF heterologous antisera raised in rabbits against human rGM-CSF were precultured (vol/vol) with the CM for 1 hour at 23°C and then added to culture dishes to test for CSF activity. TNF monoclonal antibody was precultured (vol/vol) with TNF for 1 hour at 23°C and then added to culture dishes to test the ability of fibroblasts to be stimulated to synthesize CSF.

Fig 3. (A and B) Effect of tumor necrosis factors TNF α and TNF β on granulocyte colony stimulating factor (G-CSF) and granulocyte-macrophage (GM)-CSF mRNA levels in adult lung fibroblasts. Cytoplasmic RNA (15 μ g/lane) was prepared and analyzed by formaldehyde-agarose gel electrophoresis and nylon-base paper blotting as previously described.²⁴ Lanes 1 through 5, days 0 through 4 exposure of fibroblasts to TNF α (200 U/mL), respectively; lane 6, HL-60 promyelocytes (do not express detectable CSF); lane 7, HTLV-1 immortalized T lymphocytes (SLB-1). The blot shown in A was probed with G-CSF, and the 1.6-kb hybridizing band is consistent with G-CSF mRNA; the blot in B was probed with GM-CSF, and the 0.9-kb hybridizing band is consistent with GM-mRNA. Autoradiograms were exposed for 2 days. The GM-CSF probe was gel-purified, full-length GM-CSF cDNA¹⁸ that was nick-translated to a specific activity of $>10^8$ cpm per μ g of DNA. The G-CSF is an oligonucleotide probe² that was end-labeled with γ -ATP³²p.²⁴

(SLB-1, lane 7). Levels of both G-CSF and GM-CSF mRNA were coordinately expressed in the adult fibroblasts cultured with TNF α .

We also examined the effect of TNF α on mRNA levels of G-CSF and GM-CSF in human embryonic fibroblasts (WI-38) (Figs 4A and B). These cells, similar to adult fibroblasts, constitutively contain a small amount of G-CSF and GM-CSF mRNA. The G-CSF and GM-CSF mRNA accumulation reached near maximal levels by 4-hour and 1-hour exposure to TNF α (200 U/mL), respectively, and returned toward baseline by the second day of culture.

The effect of TNF β on G-CSF and GM-CSF accumulation in lung fibroblasts was examined. Exposure of the adult fibroblasts to TNF β (200 and 400 U/mL for 2 days) only slightly stimulated levels of G-CSF and GM-CSF mRNA (Fig 5A and B).

DISCUSSION

Bagby and colleagues showed that CSF production by T lymphocytes, endothelial cells, and fibroblasts is stimulated

Fig 4. (A and B) Effect of tumor necrosis factor $\text{TNF}\alpha$ on granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage (GM)-CSF mRNA levels in embryonic lung fibroblasts. Embryonic fibroblasts (WI-38) were exposed to $\text{TNF}\alpha$ (200 U/mL) as follows: lane 1, 0 hours; lane 2, 1 hour; lane 3, 4 hours; lane 4, 12 hours; lane 5, 24 hours; lane 6, 48 hours; lane 7 contains RNA from a lung carcinoma cell line that synthesizes CSF (CSF-Ca1). Each lane contains 15 μg of RNA. The 1.6- and 0.9-kb hybridizing bands are consistent with G-mRNA and GM-mRNA, respectively. Autoradiograms were exposed for 2 days. Figure 4A was probed with the G-CSF oligonucleotide; Fig 4B was probed with GM-CSF cDNA. Methods were the same as in Fig 3.

by a soluble monocyte product, which they called monocyte-derived recruiting activity (MRA).^{15,16,25} We previously showed that $\text{TNF}\alpha$ stimulated fibroblasts to produce GM-CSF.¹⁸ The present study shows clearly that fibroblasts also can be induced to produce G-CSF. Likewise, the levels of G-CSF and GM-CSF mRNA markedly increase in the fibroblasts after these cells are exposed to $\text{TNF}\alpha$. Other investigators showed that $\text{TNF}\alpha$ stimulated endothelial cells to produce mRNA that codes for GM-CSF but not G-CSF.¹⁹ Together the findings suggest that not all mesenchymal cells are stimulated by $\text{TNF}\alpha$ to produce G-CSF. Our studies showed that after the fibroblasts were stimulated by $\text{TNF}\alpha$ to synthesize CSF, the cells continued to produce CSF for several days. This may be important in vivo to ensure continued, uninterrupted production of CSF to activate granulocytes and macrophages to contain inflammation.

We showed that $\text{TNF}\beta$ was ~1,000-fold less potent than $\text{TNF}\alpha$ in stimulation of production of CSF by fibroblasts. The $\text{TNF}\beta$ stimulated by less than twofold over baseline the levels of G-CSF and GM-CSF mRNA in fibroblasts as determined by densitometry. In contrast, levels of GM-CSF and G-CSF mRNA increased greater than eight- and three-

Fig 5. (A and B) Effect of tumor necrosis factor $\text{TNF}\beta$ on granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage (GM)-CSF mRNA levels in adult and embryonic lung fibroblasts. Methods were the same as in Fig 3. A and B show RNA from adult fibroblasts exposed for 3 days as follows: lane 1, 0 $\text{TNF}\beta$; lane 2, 200 U/mL $\text{TNF}\beta$; lane 3, 400 U/mL of $\text{TNF}\beta$; lane 4, CSF-Ca1 lung carcinoma cells that synthesize CSF. A and B were probed with a ^{32}P -labeled G-CSF oligonucleotide and a GM-CSF cDNA, respectively. The 1.6- and 0.9-kb hybridizing bands are consistent with G-mRNA and GM-mRNA, respectively. Autoradiograms were exposed for 7 days. Methods were the same as in Fig 3.

fold, respectively, in fibroblasts cultured with $\text{TNF}\alpha$. This represents the first report to our knowledge in which the two TNF proteins did not have nearly identical biologic properties. The two proteins have 30% amino acid homology, and many of the remaining differences between the two polypeptides result from conservative amino acid changes.²⁴ However, amino acids 67-109 of $\text{TNF}\alpha$ are unrelated to the corresponding region of $\text{TNF}\beta$. This apparently unrelated region of $\text{TNF}\alpha$ may specify the differences in their ability to stimulate CSF production by fibroblasts.

One of the major roles of mononuclear phagocytes in the regulation of granulopoiesis may occur through production of $\text{TNF}\alpha$ and IL 1, which recruit fibroblasts and other mesenchymal cells to produce CSF. Besides being necessary for proliferation, differentiation, and survival of hematopoietic progenitor cells, they also enhance a number of functional activities of mature granulocytes and macrophages, such as inhibition of migration, phagocytosis of microbes, oxidative metabolism, and antibody-dependent cytotoxic killing of tumor cells.⁵⁻⁸ Our data demonstrate that $\text{TNF}\alpha$ modulates the levels of both G-CSF and GM-CSF in

fibroblasts, which has several important implications. First, G-CSF and GM-CSF will be synthesized locally at inflammatory sites by activation of tissue macrophages to produce TNF α . This local G-CSF and GM-CSF can activate mature granulocytes and macrophages to migrate to inflammatory foci and, by inhibiting further migration, ensure their retention in the region of inflammation. Second, the G-CSF and GM-CSF produced as a result of TNF synthesis by macrophages at the inflammatory site may enhance proliferation of hematopoietic stem cells, leading to an increased production of the granulocytes and macrophages required to fight infection. In diseases such as rheumatoid arthritis and in

several of the collagen-vascular disorders, inflammation with its increased number of activated macrophages and granulocytes can be deleterious, causing bone and soft tissue damage. In these cases, the ability to decrease either synthesis of TNF α by macrophages or production of G-CSF and GM-CSF by TNF-stimulated mesenchymal cells at the site of inflammation may be therapeutically useful.

ACKNOWLEDGMENT

We would like to thank Suzanne Bookstaver and Regina Simon for their secretarial help, George Helfand for excellent photographic skills, and C. Nelson (Genentech) for providing the TNF antibody.

Changes in Neutrophil Surface Protein Composition Accompany Phagocytosis

By Keith M. Skubitz and Tracy K. Kinkead

Phagocytosis is a critical host defense mechanism of neutrophils. In this study, membrane protein changes occurring during phagocytosis were studied in human neutrophils using surface radiolabeling before or after phagocytosis of various target particles. Cells were labeled at the cell surface using lactoperoxidase-catalyzed iodination or neuraminidase-galactose oxidase- NaB^3H_4 , galactose oxidase- NaB^3H_4 , or periodate- NaB^3H_4 techniques. Such studies are complicated by the fact that these techniques identify many surface proteins on the phagocyte, and labeling after phagocytosis occurs often results in radiolabeling proteins of the target particle, thus making changes in cell-surface proteins more difficult to detect. Immunoprecipitation with monoclonal antibody AHN-1, which

reacts with a carbohydrate present on several human neutrophil surface proteins and inhibits phagocytosis, eliminated interference caused by radiolabeled proteins of the target particle and simplified analysis by restricting the study to a limited number of proteins. AHN-1 immunoprecipitated less radiolabeled protein from neutrophils labeled after phagocytosis of particles opsonized with IgG or complement than from cells labeled before phagocytosis. Isolation of phagocytic vesicles containing opsonized emulsified paraffin oil demonstrated that three proteins of mol wt 105,000, 140,000, and 170,000 recognized by AHN-1 were internalized in the phagocytic vesicle during phagocytosis.

THE NEUTROPHIL plays an important role in host defense against bacterial infections. One critical neutrophil host defense mechanism is phagocytosis, a process of envelopment and internalization of extracellular particles. This process can be "nonspecific" (eg, phagocytosis of latex particles) but is most efficient when the target particle is opsonized by IgG or complement. During phagocytosis, the target particle is enveloped by a vesicle derived from the plasma membrane, and large areas of the neutrophil plasma membrane are internalized with the target particles. Membrane and particle internalization occur at localized sites of cell-target contact.

Cell-surface glycoproteins play important roles in cell function and are presumably important in the process of phagocytosis as well. Indeed, neutrophils deficient in certain membrane glycoproteins have phagocytic defects.¹⁻⁴ Membrane protein changes occurring during phagocytosis have been studied in both neutrophils⁵⁻⁸ and macrophages,⁹⁻¹⁴ and many of these studies of membrane protein changes have used surface radiolabeling techniques. These studies have been complicated by the fact that the techniques identify a large number of surface proteins on the phagocyte, and labeling after phagocytosis occurs often results in radiolabeling proteins of the target particle, thus making changes in cell-surface proteins more difficult to detect. We used two different surface-labeling techniques and immunoprecipita-

tion with monoclonal antibody AHN-1 to study the surface protein composition of human neutrophils before and after phagocytosis of four different target particles. The use of immunoprecipitation with a monoclonal antibody specific for the phagocyte eliminated interference caused by radiolabeled proteins derived from the target particle and further simplified the analysis by restricting the number of surface proteins visualized. AHN-1 is an IgM monoclonal antibody that reacts with a carbohydrate epitope present on several different surface proteins of human neutrophils.¹⁵⁻¹⁷ AHN-1 also specifically inhibits phagocytosis by human neutrophils, suggesting that one or more of the surface proteins recognized by AHN-1 may play a role in this process.¹⁸ We found that AHN-1 immunoprecipitated less radiolabeled protein from neutrophils labeled at the cell surface with ^{125}I or ^3H after phagocytosis of particles opsonized with IgG or complement than from cells labeled before phagocytosis of the same target particles. Our results may have been due to internalization of surface proteins, resulting in fewer of these proteins on the surface, or to some other effect that altered the efficiency of protein labeling, such as a conformational change. To characterize these surface protein changes further, we isolated phagocytic vesicles from neutrophils labeled at the cell surface with ^{125}I or ^3H before or after phagocytosis of opsonized emulsified paraffin oil droplets. The proteins recognized by AHN-1 were shown to be internalized during phagocytosis by both radiolabeling techniques. These results demonstrate that these proteins are closely associated with the process of phagocytosis and further characterize their fate during particle ingestion.

MATERIALS AND METHODS

Cell preparation. Normal peripheral blood neutrophils were prepared by a modification of the methods of Boyum and Craddock and colleagues^{19,20} as previously described. Cells were suspended at appropriate concentrations in phosphate-buffered saline (PBS), pH 7.4 or Hanks' balanced salt solution (HBSS), pH 7.4 (GIBCO Laboratories, Grand Island, NY) as indicated. Differential cell counts on Wright's-stained cells routinely revealed >95% neutrophils.

Materials. Anti-human neutrophil monoclonal antibodies AHN-1 and AHN-1.1 were produced as previously described.¹⁵ AHN-1.1 is an IgM monoclonal antibody with a similar affinity for

lacto-*N*-fucopentaose III (LNF III) as AHN-1.^{16,17} Ascites fluid from mice bearing the appropriate IgM-secreting hybridomas was heat-inactivated at 56°C for 30 minutes and then centrifuged at 100,000 g for 1 hour at 4°C prior to use. Antibody 60.3, a CDw18 monoclonal antibody,² was a gift of Drs P. Beatty and J. Harlan (University of Washington, Seattle).

Sheep erythrocytes sensitized with rabbit IgG (EA7S), sheep erythrocytes sensitized with rabbit IgG, guinea pig C1, and human C4, C2, and C3 (EAC423), and unopsonized sheep erythrocytes (E) were obtained from Cordis Laboratories, Miami. Before use, sheep erythrocytes were washed once in PBS at 23°C and resuspended at the desired concentration in HBSS containing 0.2% bovine serum albumin (BSA) (Sigma Chemical, St Louis). Latex beads, 2.0 μ m in diameter, were obtained from Polyscience, Warrington, PA. Before use, latex particles were washed once in PBS, incubated for 30 minutes at 23°C in HBSS containing 5% BSA, washed again in PBS, and then suspended at the desired concentration in HBSS containing 0.2% BSA (HBSS-BSA). Zymosan (ICN Pharmaceuticals, Cincinnati) was opsonized with fresh human serum (2 mg/mL) for 30 minutes at 37°C, washed once with PBS, and resuspended in HBSS as described above.

¹²⁵I Radiolabeling. Neutrophils were radiolabeled with ¹²⁵I at the cell surface using lactoperoxidase as previously described^{21,22} with minor modifications. Radiolabeling was performed before or after phagocytosis of various target particles as indicated. In brief, 1 mCi of Na¹²⁵I (100 mCi/mL carrier-free, Amersham, Arlington Heights, IL) was added to 10⁷ neutrophils in 1 mL of PBS containing 20 mmol/L of glucose, 0.22 U of lactoperoxidase (Sigma), and 0.02 U of glucose oxidase type V (Sigma), at 0°C, and the cells were then incubated for 25 minutes at 0°C. The reaction was terminated by adding 10 mL of 0°C PBS and then adding diisopropylfluorophosphate (DFP) (Sigma) to 5 mmol/L. After 10 minutes at 0°C, the cells were washed twice with 10 mL of PBS at 0°C. In some cases, as indicated, cells were washed twice with 10 mL of PBS at 0°C without DFP treatment, resuspended in 100 μ L of HBSS, and mixed with target particles for phagocytosis as described below. In these cases, the cells were treated with DFP after phagocytosis but before solubilization.

NaB³H₄-Radiolabeling. Neutrophils were labeled with ³H at the cell surface using NaB³H₄ as previously described with minor modifications.²³⁻²⁵ Radiolabeling was performed before or after phagocytosis of various target particles as indicated. Three different methods were used. In the first two methods, 2 $\times$ 10⁷ neutrophils were incubated with 5 U of galactose oxidase Type V (E.C. 1.1.3.9.) (Sigma) with or without 1 U of neuraminidase Type X (Sigma) in 1 mL of HBSS at 37°C for 30 minutes. The cells were then washed twice with 1 mL of PBS at 0°C and resuspended in 500 μ L of PBS at 23°C. Two mCi of NaB³H₄ (Specific activity 15 Ci/mmol, Research Products International, Mount Prospect, IL) in 10 μ L of 0.1 mol/L of NaOH was added, and the mixture was then incubated at 23°C for 30 minutes. The cells were washed twice with PBS at 0°C. In the third method, 2 $\times$ 10⁷ neutrophils were incubated in PBS containing 1 mmol/L of NaIO₄ for 10 minutes at 0°C in the dark. The cells were then washed twice with PBS at 0°C, resuspended in 500 μ L of PBS at 23°C and treated with NaB³H₄ as described above. Cells were treated with DFP before solubilization as described for ¹²⁵I-labeling.

Phagocytosis. Phagocytosis of four different target particles was performed before or after radiolabeling, as indicated. Neutrophils, 2 $\times$ 10⁷ in 200 μ L of HBSS, were mixed with 100 μ L of HBSS-BSA containing 2 $\times$ 10⁸ sheep erythrocytes, 2 $\times$ 10⁸ latex particles, or 300 μ g of opsonized zymosan, and the mixture was incubated for 30 minutes at 37°C. When neutrophils were radiolabeled before phagocytosis, phagocytosis was terminated by adding 1

mL of PBS at 0°C and centrifuging at 400 g for 6 minutes. When neutrophils were radiolabeled after phagocytosis, phagocytosis was terminated by adding PBS and DFP as described above.

Preparation of phagocytic vesicles. Phagocytic vesicles of neutrophils labeled at the cell surface were prepared using opsonized Oil Red O particles as previously described²⁶⁻²⁹ with minor modifications. Opsonized Oil Red O-containing particles (ORO) were prepared as described, suspended in 1 mL of HBSS, and aliquots were frozen and stored at -20°C for no longer than 1 month before use.

Phagocytosis was performed in 50-mL polypropylene tubes either before or after radiolabeling. Neutrophils, 3 $\times$ 10⁷/mL, were suspended in 4 mL of HBSS containing 10 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) (GIBCO), pH 7.2, and prewarmed for 15 minutes at 37°C. Freshly vortexed prewarmed ORO particles, 1.6 mL, were then added, and the mixture was incubated for 30 minutes at 37°C with frequent mixing. Phagocytosis was stopped by adding 40 mL of 0°C saline containing 1 mmol/L of *N*-ethylmaleamide (Sigma). Uningested ORO particles were then removed by centrifugation at 400 g for 6 minutes at 4°C. The cell pellet was resuspended and washed twice by suspending in 50 mL of PBS at 0°C and centrifuging at 400 g for 6 minutes and then was washed once with 20 mL of homogenization buffer [0.34 mol/L of sucrose containing 0.5 mg/mL BSA, 2 mmol/L of phenylmethylsulfonylfluoride (PMSF) (Sigma), and 10 mmol/L of HEPES, pH 7.2] at 4°C.

Phagocytic vesicles were then prepared by suspending the cells in 0.8 mL of homogenization buffer at 0°C in a Potter-Elvehjem homogenizer with a tight Teflon pestle (Kontes Glass, Vineland, NJ) and homogenized. Homogenization consisted of 10 up-and-down strokes during 1 minute with a Wheaton Overhead stirrer (Wheaton Instruments, Millville, NJ) set at a speed of 4. The homogenate was then centrifuged at 400 g for 6 minutes, and the supernatant was layered over a discontinuous gradient composed of 0.8 mL each of 50%, 45%, and 35% (wt/vol) sucrose containing 0.05 mg/mL of BSA, and 10 mmol/L of HEPES, pH 7.2. The supernate was then overlaid with 8.6% sucrose containing 10 mmol/L of HEPES, pH 7.2, and the samples were then centrifuged at 100,000 g_{av} for 60 minutes at 4°C. The phagocytic vesicles were then collected from the surface, and the plasma membrane fraction was recovered from the interface between the 35% and 45% sucrose layers. The plasma membrane fraction was washed by diluting with 5 vol of 10 mmol/L of HEPES, pH 7.2, containing 2 mmol/L of PMSF and centrifuged at 27,000 g_{av} for 45 minutes at 4°C.

When cells were surface-labeled after phagocytosis, phagocytosis was performed exactly as described above except that following the *N*-ethylmaleamide wash the cells were washed twice with PBS at 0°C and resuspended in the appropriate buffers for radiolabeling as described above. Following radiolabeling, the cells were washed in 20 mL of homogenization buffer, and phagocytic vesicles were prepared as described above.

Immunoprecipitation and polyacrylamide gel electrophoresis. Neutrophils (1 to 2 $\times$ 10⁷) labeled with ¹²⁵I or ³H and treated with DFP as described above were suspended in 1.0 mL of cell solubilization buffer (20 mmol/L of Tris-HCl, pH 7.6, 150 mmol/L of NaCl, 0.5% Nonidet P-40, 0.02% Na₃N, and 2 mmol/L of PMSF) and incubated on ice for 1 hour.¹⁵ Radiolabeled proteins of phagocytic vesicles and plasma membrane fractions were also solubilized in solubilization buffer as described above. The suspensions were then centrifuged at 100,000 g for 1 hour at 4°C. The resulting supernatants were used for immunoprecipitation or analyzed by NaDodSO₄ (SDS-PAGE). Immunoprecipitation was performed as previously described except that extracts were not preabsorbed with *Staphylococcus aureus*.¹⁵ SDS-PAGE and autoradiography were performed as described.^{15,30}

RESULTS

Changes in surface proteins during phagocytosis detected by ^{125}I -labeling. Changes in neutrophil surface proteins occurring during phagocytosis were examined by surface-labeling with ^{125}I using lactoperoxidase, before and after phagocytosis of various target particles. Analysis of radiolabeled proteins in extracts of cells labeled with ^{125}I before and after phagocytosis revealed a complex pattern of many radiolabeled proteins (data not shown). Analysis was further complicated by the appearance of radiolabeled proteins from the target particles. We used immunoprecipitation by the granulocyte-specific monoclonal antibody AHN-1 for better definition of changes in surface proteins occurring during phagocytosis.¹⁵ AHN-1 recognizes a carbohydrate epitope present on several surface proteins of human neutrophils^{16,17} and also inhibits phagocytosis by human neutrophils.¹⁸ AHN-1 immunoprecipitated ^{125}I -labeled proteins of ~105,000 and 135,000 to 190,000 daltons from resting neutrophils (Fig 1, Lane A) as previously described.¹⁵⁻¹⁷ The higher mol wt protein complex migrated as a broad band and was often resolved into two separate proteins with mol wt of ~140,000 and ~170,000 as previously described.¹⁶ To test the effect of the process of phagocytosis on surface proteins previously labeled with ^{125}I , cells were labeled with ^{125}I , washed, and then allowed to phagocytose test particles. The patterns of radiolabeled proteins immunoprecipitated by AHN-1 from cells labeled prior to phagocytosis of EA7S (Fig 1, lane B), EAC423 (Fig 1, lane C), opsonized zymosan (Fig 1, lane D), or latex particles (Fig 1, lane E) were similar to that from cells solubilized prior to phagocytosis (Fig 1, lane A).

In contrast, immunoprecipitates from neutrophils labeled with ^{125}I after phagocytosis were strikingly different. Immunoprecipitates from cells labeled after phagocytosis of EA7S (Fig 1, lane F), EAC423 (Fig 1, lane G), or opsonized zymosan (Fig 1, lane H) contained almost no detectable radiolabeled 140-kd protein (Fig 1, arrow). In some experiments, the intensity of the 105-kd protein decreased as well. Phagocytosis of latex particles (Fig 1, lane I) or unopsonized RBCs (E) (data not shown) before radiolabeling had little effect on the radiolabeled proteins immunoprecipitated by AHN-1. Phagocytosis of opsonized or unopsonized ORO particles before ^{125}I -labeling resulted in a decrease in intensity of both the 140- to 170-kd and 105-kd proteins immunoprecipitated by AHN-1, although this decrease was less marked than that observed with EA7S or EAC423 (data not shown). Normal mouse serum (NMS) did not immunoprecipitate these major radiolabeled proteins from ^{125}I -labeled resting neutrophils (Fig 1, lane N) or any of the other extracts tested (data not shown). Similarly, AHN-1 did not specifically immunoprecipitate any radiolabeled proteins from extracts of target particles labeled with ^{125}I using lactoperoxidase (Fig 1, lanes J through M). Immunoprecipitates using AHN-1.1 were identical to those using AHN-1 (data not shown). Microscopical examination (Table 1) confirmed that neutrophils readily phagocytosed opsonized RBCs but not unopsonized cells. The latex particles were less efficiently phagocytosed. More than 50% of neutrophils

Fig 1. Immunoprecipitation by AHN-1 of radiolabeled proteins of neutrophils labeled with ^{125}I at the cell surface before and after phagocytosis. Neutrophils were surface labeled with ^{125}I using lactoperoxidase before or after phagocytosis of various test particles, solubilized, and immunoprecipitated as described in the text. Immunoprecipitates were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 5% to 15% linear gradient polyacrylamide gel and autoradiography as described in the text. Approximately 2×10^6 neutrophil and 2×10^7 RBC equivalents were added to each immunoprecipitation reaction shown in lanes A through I and N. Approximately 2×10^7 RBC equivalents (the same amount present in lanes A through I) were added to each immunoprecipitation reaction shown in lanes J through M. Lanes A through M: immunoprecipitates with monoclonal antibody AHN-1; lane A: ^{125}I labeled resting neutrophils; lanes B through E: cells labeled before phagocytosis; lanes F through I: cells labeled after phagocytosis; and lanes J through M: target particles labeled with ^{125}I . Phagocytic targets were: lanes B, F, and J—EA7S; lanes C, G, and K—EAC423; lanes D, H, and L—opsonized zymosan; and lanes E, I, and M—latex beads coated with BSA. Each extract was also immunoprecipitated with normal mouse serum (NMS). Lane N shows the immunoprecipitate with NMS of the same extract shown in lane B immunoprecipitated with AHN-1. Immunoprecipitates with NMS from the extracts used in lanes A through I appeared similar to lane N. Proteins used as mol-wt standards were myosin heavy chain, 200,000; *Escherichia coli* β -galactosidase, 116,000; phosphorylase B, 97,400; bovine serum albumin, 66,000; and ovalbumin, 45,000. Two replicate experiments gave similar results.

Table 1. Phagocytosis of Target Particles

Target	No. of Target Particles per Neutrophil						
	0	1	2	3	4	5	>5
E	96 $\pm$ 2	4 $\pm$ 2	0	0	0	0	0
EA7S	31 $\pm$ 5	26 $\pm$ 2	20 $\pm$ 3	13 $\pm$ 3	6 $\pm$ 2	3 $\pm$ 1	2 $\pm$ 1
EAC423	17 $\pm$ 1	16 $\pm$ 4	10 $\pm$ 8	16 $\pm$ 3	15 $\pm$ 2	9 $\pm$ 2	12 $\pm$ 2
Latex	50 $\pm$ 4	27 $\pm$ 5	12 $\pm$ 3	7 $\pm$ 3	2 $\pm$ 1	2 $\pm$ 2	1 $\pm$ 1

Phagocytosis was performed as described in the text, and the number of target particles ingested by each neutrophil was determined by light microscopy. Results are reported as the mean $\pm$ SD of three determinations.

(Percentage of Neutrophils Phagocytosing Indicated No. of Target Particles)

incubated with ORO contained identifiable ORO particles of various sizes (data not shown).

Because neutrophils contain enzyme systems capable of halogenating proteins,^{6,31} we performed control experiments in which Na^{125}I was added to the labeling mixture but lactoperoxidase was omitted (Fig 2). AHN-1 did not immunoprecipitate any radiolabeled proteins from extracts of resting neutrophils labeled for 25 minutes at 0°C in the presence of Na^{125}I but not lactoperoxidase (Fig 2, lane A). In contrast, when neutrophils were allowed to phagocytose EA7S for 30 minutes at 37°C and were cooled to 0°C and then labeled as above with Na^{125}I without lactoperoxidase, AHN-1 did immunoprecipitate radiolabeled proteins (Fig 2, lane C), although the quantity of ^{125}I -labeled proteins immunoprecipitated was much less than that observed when the radiolabeling mixture contained lactoperoxidase. Indeed, it was necessary to overexpose lanes B and E of the autoradiograph markedly to demonstrate the autoiodination shown in lanes C and D. However, the electrophoretic patterns of ^{125}I -labeled proteins in AHN-1 immunoprecipitates from cells radiolabeled after phagocytosis of EA7S was similar

Fig 2. Immunoprecipitation with AHN-1 of neutrophil proteins radiolabeled with ^{125}I with and without lactoperoxidase. Neutrophils were labeled with ^{125}I for 25 minutes at 0°C as described in the text, except that for some reactions lactoperoxidase was omitted and in others NaCN and NaN_3 were added as indicated. Radiolabeled proteins were immunoprecipitated with monoclonal antibody AHN-1 and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 5% to 15% linear gradient polyacrylamide gel and autoradiography as described in the text. Lanes A and B: Resting cells labeled without (lane A) or with (lane B) lactoperoxidase. Cells were also allowed to phagocytose EA7S without (lane C) and with (lane D) 1 mmol/L of NaCN and 1 mmol/L of NaN_3 and then were washed once in phosphate-buffered saline (PBS) at 0°C and labeled with ^{125}I without lactoperoxidase. Lane E: cells labeled with lactoperoxidase after phagocytosis of EA7S. Immunoprecipitation reactions in lanes B and E each contained 1×10^6 cell equivalents, whereas those in lanes A, C, and D each contained 2.5×10^6 cell equivalents. When 1×10^6 cell equivalents were used for the immunoprecipitation reactions in lanes A, C, and D, less radiolabeled protein was visualized. Lane B corresponds to Fig 1, lane B. Lane E corresponds to Fig 1, lane F. The autoradiograph was deliberately overexposed to demonstrate the autoradiolabeling in lanes C and D. Mol-wt standards were the same as in Fig 1. A duplicate experiment gave similar results.

whether lactoperoxidase was present (Fig 1, lane F) or absent (Fig 2, lane C). Similar studies of rabbit peritoneal polymorphonuclear leukocytes showed that 1 mmol/L of NaCN inhibited autoiodination during phagocytosis.⁶ In the present study, however, the addition of 1 mmol/L of NaCN and 1 mmol/L of NaN_3 did not eliminate autoiodination of the proteins recognized by AHN-1 (Fig 2, lane D).

Changes in surface proteins during phagocytosis detected by ^3H labeling. Changes in neutrophil surface glycoproteins occurring during phagocytosis were also examined by NaB^3H_4 labeling using three different techniques. Various proteins were radiolabeled by NaB^3H_4 following pretreatment with neuraminidase and galactose oxidase (NA + GO) (Fig 3, lane B), galactose oxidase alone (GO) (Fig 3, lane C), or NaIO_4 (Fig 3, lane D), but none was labeled without pretreatment (Fig 3, lane A). In contrast to the autoradiolabeling observed with ^{125}I labeling, the addi-

Fig 3. Surface glycoproteins of neutrophils labeled with ^3H before or after phagocytosis. Neutrophils were labeled with ^3H before (lanes A through D, I through L, and T) or after (lanes E through H, and M through P) phagocytosis of EA7S, solubilized, and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 5% to 15% gradient polyacrylamide gel and autoradiography as described in the text. Lanes A through H: Cell extracts ($\sim 10^6$ cell equivalents per lane). Lanes I through T: Immunoprecipitates ($\sim 8 \times 10^6$ neutrophil cell equivalents per immunoprecipitation reaction in lanes I through P and T, or $\sim 8 \times 10^6$ RBC equivalents in lanes Q through S). Lanes I through S: Immunoprecipitates using AHN-1. Lane T: Immunoprecipitate using NMS. Cells were labeled with NaB^3H_4 following treatment with NA + GO (lanes B, F, J, N, and T), GO (lanes C, G, K, and O), NaIO_4 (lanes D, H, L, and P), or no pretreatment (lanes A, E, I, and M). EA7S target cells were also immunoprecipitated with AHN-1 after radiolabeling with ^3H using NA + GO (lane Q), GO (lane R), and NaIO_4 (lane S). Immunoprecipitates from extracts of cells labeled using GO or NaIO_4 using NMS resembled that shown in lane T. Mol-wt standards were the same as in Fig 1 with the addition of carbonic anhydrase, 29,000. A duplicate experiment gave similar results.

tion of NaB^3H_4 to neutrophils before or after phagocytosis, without pretreatment with $\text{NA} + \text{GO}$, GO , or NaIO_4 , did not result in radiolabeling of any proteins (Fig 3, lanes A and E, and data not shown). The electrophoretic patterns of ^3H -labeled proteins were similar to those previously reported.²³ Some changes in the proteins radiolabeled occurred when cells were labeled by these same techniques after phagocytosis of EA7S (Fig 3, lanes E through H). Several of these ^3H -labeled proteins were specifically immunoprecipitated by AHN-1 (Fig 3, lanes I through P) but not by normal mouse serum (Fig 3, lane T). AHN-1 immunoprecipitated much less ^3H -labeled protein in the mol-wt range of $\sim 140,000$ from extracts of cells labeled after phagocytosis of EA7S (Fig 3, arrow), similar to that observed with ^{125}I surface labeling. These changes could not be attributed to immunoprecipitation of radiolabeled target proteins (Fig 3, lanes Q through S). Although a small amount of radiolabeled protein was immunoprecipitated from EA7S labeled with the $\text{NA} + \text{GO}-\text{NaB}^3\text{H}_4$ technique by both AHN-1 (Fig 3, lane Q) and NMS (not shown), relatively little or no ^3H -labeled protein of this mol wt was immunoprecipitated by AHN-1 from neutrophils labeled by the same technique after phagocytosis of EA7S (Fig 3, lane N). Immunoprecipitates using AHN-1.1 were identical to those using AHN-1 (data not shown).

Because treatment with $\text{NA} + \text{GO}$ and NaB^3H_4 was the most effective method of labeling neutrophil surface glycoproteins recognized by AHN-1 with ^3H , this technique was used to label cells with ^3H before and after phagocytosis of the same target particles studied with ^{125}I labeling. As with ^{125}I labeling, the patterns of radiolabeled proteins immunoprecipitated by AHN-1 from cells labeled with ^3H prior to phagocytosis of EA7S, EAC423, or latex particles were similar to that obtained from cells labeled and solubilized without phagocytosis (data not shown). Immunoprecipitates with AHN-1 of cells labeled after phagocytosis of EA7S (Fig 4, lane C) or EAC423 (Fig 4, lane D) contained markedly less of the ~ 140 kD ^3H -labeled protein (Fig 4, arrow) than did cells labeled before phagocytosis (Fig 4, lanes A and B). As with ^{125}I labeling, phagocytosis of latex particles (Fig 4, lane E) or E (data not shown) before radiolabeling had little effect on the radiolabeled proteins immunoprecipitated by AHN-1. Normal mouse serum did not immunoprecipitate radiolabeled proteins from any of the samples (data not shown). Immunoprecipitates using AHN-1.1 were identical to those using AHN-1.

Analysis of surface protein transport into phagocytic vesicles by ^{125}I radiolabeling. During phagocytosis, the ingested particle is enveloped by a vesicle derived from the plasma membrane. To define the changes in neutrophil surface proteins during phagocytosis further, we isolated phagocytic vesicles from neutrophils using the technique of Stossel and colleagues.²⁶⁻²⁸ When phagocytic vesicles were prepared from neutrophils labeled at the cell surface with ^{125}I before phagocytosis of ORO particles, most of the major ^{125}I -labeled proteins found on the resting cell (Fig 5, lane A) were found in the phagocytic vesicles (Fig 5, lane B). Many of the ^{125}I -labeled proteins present in these phagocytic vesicles were specifically immunoprecipitated by AHN-1 (Fig 5,

Fig 4. Immunoprecipitation by AHN-1 of radiolabeled surface glycoproteins of neutrophils labeled with ^3H before or after phagocytosis of various target particles. Neutrophils were labeled with ^3H using $\text{NA} + \text{GO}$ before or after phagocytosis of various target particles, solubilized, immunoprecipitated, analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 7.5% polyacrylamide gel, and visualized by autoradiography as described in the text. A 7.5% gel was used for better resolution of the higher mol-wt proteins immunoprecipitated by AHN-1. Lane A: Resting cells. Lane B: Cells labeled after incubation in Hanks' balanced salt solution (HBSS) under conditions of phagocytosis but in the absence of target particles. Lanes C through E: cells labeled after phagocytosis of EA7S (lane C), EAC423 (lane D), or latex particles (lane E). Mol-wt standards were the same as in Fig 3. A duplicate experiment gave similar results.

lane C) but not by normal mouse serum (Fig 5, lane D). Immunoprecipitates from the plasma membrane fraction were similar but contained less radiolabeled material (not shown). In contrast, phagocytic vesicles prepared from neutrophils that phagocytosed ORO particles before radiolabeling contained little radiolabeled material (Fig 5, lane E) and no radiolabeled proteins were immunoprecipitated by AHN-1 or NMS (Fig 5, lanes F and G). As expected, immunoprecipitates using AHN-1.1 were identical to those using AHN-1 (not shown). Similar results occurred when phagocytic vesicles were prepared using nonopsonized ORO (data not shown).

Analysis of surface protein transport into phagocytic vesicles by ^3H radiolabeling. Transport of surface proteins into phagocytic vesicles was also analyzed after radiolabeling with ^3H using $\text{NA} + \text{GO}$. As with ^{125}I labeling, phagocytic vesicles prepared from neutrophils labeled with ^3H before phagocytosis of ORO particles (Fig 6, lane B) contained most of the major ^3H -labeled proteins present on resting cells (Fig 6, lane A). Phagocytic vesicles prepared from cells that were ^3H labeled after phagocytosis contained little ^3H -labeled protein (Fig 6, lane E). Many of the major ^3H -labeled proteins present in the phagocytic vesicles were specifically immunoprecipitated by AHN-1 (Fig 6, lane C) but not by normal mouse serum (Fig 6, lane D). Again,

Fig 5. Isolation of phagocytic vesicles from neutrophils surface labeled with ^{125}I . Neutrophils were radiolabeled at the cell surface with ^{125}I using lactoperoxidase before or after phagocytosis of ORO particles. Phagocytic vesicles were then isolated, solubilized, and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 10% polyacrylamide gel and autoradiography as described in the text. Lane A: Surface-labeled resting neutrophils. Lanes B through D: ^{125}I -Labeling before phagocytosis. Lanes E through G: ^{125}I -Labeling after phagocytosis. Lanes B and E: Extracts of phagocytic vesicles. Extracts of phagocytic vesicles were immunoprecipitated with AHN-1 (lanes C and F) or normal mouse serum (lanes D and G). Equivalent volumes of the phagocytic vesicle fractions were added to lanes B and E and to the immunoprecipitation reactions for lanes C, D, F, and G. Mol-wt standards were the same as in Fig 3. A duplicate experiment gave similar results.

immunoprecipitates using AHN-1.1 were identical to those using AHN-1 (not shown). Similar results occurred when phagocytic vesicles were prepared using nonopsonized ORO (data not shown).

DISCUSSION

Phagocytosis is an important defense mechanism of granulocytes and mononuclear phagocytes. The process of phagocytosis involves particle recognition, binding, and ingestion. During phagocytosis, the plasma membrane of the phagocyte gradually envelops the surface of the target particle and then the invaginated membrane fuses, separating from the plasma membrane to create a phagocytic vesicle. These vesicles then fuse with lysosomes to create phagolysosomes. The membrane of the phagocytic vesicle is clearly derived from the phagocyte's plasma membrane, but the composition of neither membrane is well defined. Glycoproteins of the plasma membrane are important in cell function, and several surface glycoproteins are presumably involved in phagocytosis. A better understanding of the mechanism of phagocytosis will require more detailed knowledge of the composition of the plasma membrane and the phagocytic vesicle and the changes in membrane composition that occur during phagocytosis.

The fates of human neutrophil surface glycoproteins dur-

Fig 6. Isolation of phagocytic vesicles from neutrophils surface labeled with ^3H . Neutrophils were radiolabeled with ^3H before or after phagocytosis of ORO particles using NaB^3H_4 after treatment with NA + GO as described in the text. Phagocytic vesicles were then isolated, solubilized, and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a 7.5% polyacrylamide gel and autoradiography as described in the text. Lane A: Surface-labeled resting neutrophils. Lanes B through D: ^3H Labeling before phagocytosis. Lanes E through G: ^3H -labeling after phagocytosis. Lanes B and E: Extracts of phagocytic vesicles. Extracts of phagocytic vesicles were immunoprecipitated with AHN-1 (lanes C and F) or normal mouse serum (lanes D and G). Equivalent volumes of the phagocytic vesicle fractions were added to lanes B and E and to the immunoprecipitation reactions for lanes C, D, F, and G. Mol-wt standards were the same as in Fig 1. A duplicate experiment gave similar results.

ing phagocytosis are not well defined. Studies of phagocytic vesicles of cultured murine peritoneal macrophages, using a technique of intralysosomal iodination, have suggested that following antibody- and complement-independent phagocytosis of latex beads, the membrane proteins accessible to lactoperoxidase-catalyzed iodination on the luminal surface of the phagolysosome and on the external face of the plasma membrane are similar.¹⁰ A companion study provided evidence for continuous bidirectional flow of membrane polypeptides between the plasma membrane and the secondary lysosome.¹¹ Studies of both rabbit polymorphonuclear leukocytes and alveolar macrophages showed that the activities of five separate specific transport systems were unaffected by phagocytosis, even after 35% to 50% of the surface membrane had been internalized.⁵ This work supported the concept that the membrane is mosaic in character, with geographically separate transport and phagocytic sites, and that during phagocytosis, transport sites are preserved on the surface despite the internalization of a large amount of the plasma membrane.⁵ Further studies suggested that colchicine-sensitive sites were involved in this differential internalization, since colchicine treatment resulted in a decrease in surface transport sites during phagocytosis.⁷ Other workers studying human neutrophils found a decreased but differentially reduced activity of transport sites for potassium and lysine following phagocytosis of zymosan or latex, also

favoring a mosaic membrane structure.⁸ Other studies of antibody-dependent phagocytosis of lipid vesicles by RAW264 macrophages found a loss of surface Fc-receptor activity with no loss of C3b-receptor activity, again demonstrating selectivity in surface protein internalization during phagocytosis.¹² These same workers observed a loss of both Fc- and C3b-receptor activity from the cell surface following the uptake of latex beads, a comparatively nonspecific phagocytic process. Similar findings were observed in studies of murine macrophages.^{13,14} In addition, using the techniques of ¹²⁵I surface labeling and two-dimensional gel electrophoresis,⁹ an ~140-kd protein was observed to disappear from the surface of RAW264 macrophages following phagocytosis of opsonized liposomes, providing further evidence that phagocytosis leads to a modification of cell-surface protein composition.

Willinger and associates⁶ used lactoperoxidase-catalyzed iodination and phagocytosis of ORO to study the fate of surface proteins of rabbit polymorphonuclear leukocytes during phagocytosis. They found a nonrandom interiorization of ¹²⁵I-labeled surface proteins during phagocytosis with a reduction in the amount of three proteins of mol wt ~100,000, 180,000, and 215,000 on the cell surface after phagocytosis. These same proteins also appeared to be translocated to the phagosome during phagocytosis. The 100- and 180-kd proteins transported to the phagosome during phagocytosis by rabbit neutrophils may correspond to the 105-kd and 135- to 190-kd proteins recognized by AHN-1 in human neutrophils. Two similar studies on the L cell, a murine fibroblast, also analyzed the fate of external membrane proteins during phagocytosis.^{22,32} Both studies found all the proteins identified by ¹²⁵I surface labeling in isolated phagosomes following phagocytosis of latex beads when cells were grown in suspension. L cells grown in monolayer cultures contained only two major surface-iodinated proteins, one of which was found in phagosomes.³²

We used two techniques of cell-surface labeling to study changes in the surface protein composition of human neutrophils during phagocytosis. Such studies with ¹²⁵I surface labeling have been difficult because: (a) When stimulated, neutrophils can iodinate cellular proteins in the absence of added lactoperoxidase by their intrinsic halogenating systems³¹; (b) analysis by SDS-PAGE of human neutrophils surface labeled with ¹²⁵I using lactoperoxidase reveals a complex pattern of radiolabeled proteins; and (c) ¹²⁵I labeling after phagocytosis results in ¹²⁵I-labeled proteins derived from the target particle, further complicating analysis. We used immunoprecipitation and cell-surface labeling with both ¹²⁵I using lactoperoxidase and also ³H using NA + GO, GO, or NaIO₄, to study changes in the surface protein composition of human neutrophils during phagocytosis. Protein radiolabeling with ³H was only observed following exogenous enzyme or NaIO₄ treatment, even in stimulated neutrophils. Because the electrophoretic pattern of radiolabeled proteins obtained from surface-labeled neutrophils was complex, we used immunoprecipitation with the granulocyte-specific monoclonal antibody of AHN-1 to restrict our analysis to a subset of surface proteins. AHN-1 binds an oligosaccharide epitope present on several surface glycopro-

teins of human neutrophils¹⁷ but it had no reactivity with any of the target particles, thus eliminating interference with radiolabeled target proteins. Analysis of the surface proteins recognized by AHN-1 is of particular interest because AHN-1 inhibits phagocytosis by human neutrophils,¹⁸ suggesting that one or more of these proteins is intimately involved in the process of phagocytosis.

We found that AHN-1 immunoprecipitated less of certain ¹²⁵I-labeled proteins when neutrophils were surface labeled after phagocytosis. In addition, there appeared to be a selective decrease in two ¹²⁵I-labeled proteins of ~140 kd and 170 kd after phagocytosis of IgG or C3 opsonized targets but not after phagocytosis of latex particles or ORO. These results were confirmed by a similar analysis of cells labeled at the surface with NaB³H₄ using three different labeling techniques. Similar studies using the CDw18 monoclonal antibody 60.3 revealed that 60.3 also immunoprecipitated less of the ¹²⁵I-labeled α and β chains of this protein family from cells surface labeled after phagocytosis (data not shown). Other studies have reported that phagocytosis results in an increase in surface CR3 recognized by the Mol monoclonal antibody, due to translocation to the surface from intracellular pools.^{33,34} The decrease we observed in the quantity of ¹²⁵I-labeled proteins immunoprecipitated by 60.3 from cells labeled after phagocytosis could be due to less efficient radiolabeling due to the presence of the target particles (for example, steric hindrance or receptor occupancy).

The changes we observed in the proteins immunoprecipitated by AHN-1 may have been due to internalization of proteins resulting in fewer of these proteins exposed on the cell surface, binding of target particles resulting in less efficient radiolabeling, or some other conformational change resulting in less efficient labeling of the proteins under study. To define the fate of these proteins during phagocytosis further, we isolated phagocytic vesicles from neutrophils surface labeled before or after phagocytosis of ORO particles, using the technique of Stossel and colleagues.²⁶⁻²⁹ These studies, using either ¹²⁵I or ³H labeling, demonstrated that three proteins of ~105 kd, 140 kd, and 170 kd recognized by AHN-1 were internalized in the phagocytic vesicle. Similar studies revealed that the β chain and all three α chains recognized by the CDw18 monoclonal antibody 60.3 were also internalized into ORO containing phagocytic vesicles (data not shown). The apparently selective internalization of the 140-kd and 170-kd proteins recognized by AHN-1 compared with the 105-kd protein during phagocytosis of EA7S or EAC423 could be due to several possibilities: (a) The 140-kd and 170-kd proteins were internalized at a greater rate than was the 105-kd protein; (b) all three proteins were internalized at the same rate, but resting cells contain less of the 140-kd and 170-kd proteins on the surface than of the 105-kd protein; (c) the target particles bound more closely to the 140-kd and 170-kd proteins, making them less accessible to radiolabeling; or (d) some other conformational change during particle binding and internalization altered the labeling efficiency of the proteins. We did not observe more internalization of the ~140-kd protein into the phagocytic vesicle than of the 105-kd or 170-kd proteins

during phagocytosis of ORO. Similarly, the relative amounts of ^{125}I -labeled 105-kd, 140-kd, and 170-kd proteins recognized by AHN-1 remaining in the plasma membrane fraction of cells labeled at the surface before phagocytosis of ORO was similar to that observed in resting cells. Thus, our results with phagocytosis of ORO do not provide evidence for selective internalization of the 140-kd protein in comparison to the 105-kd and 170-kd proteins or for the presence of a greater number of 105-kd and 170-kd proteins than 140-kd proteins on the surface of resting cells coupled with equal rates of internalization. However, the whole cell immunoprecipitation studies described in Fig 1 did not reveal a selective decrease in the quantity of ^{125}I -labeled 140-kd protein immunoprecipitated by AHN-1 from cells labeled after phagocytosis of ORO. The selective decrease in radiolabeled 140-kd and 170-kd proteins immunoprecipitated by AHN-1 from cells labeled at the surface after phagocytosis of EA7S or EAC423 compared with resting cells may be due to a selective decrease in labeling efficiency of these proteins resulting from target binding or a subsequent step in phagocytosis.

In summary, this report demonstrates that qualitative changes in the surface membrane composition of human neutrophils occur during phagocytosis. Some of the molecules that take part in this alteration have been identified using the granulocyte-specific monoclonal antibody AHN-1. Similar studies using other monoclonal antibodies that react with the phagocyte surface may be informative. These results confirm that a nonrandom internalization of surface proteins occurs during phagocytosis by human neutrophils, as has been observed in studies of some other cell systems^{5-9,12-14,32} but not in others.^{10,22,32} Such nonrandom internalization of surface proteins may be important in preserving other independent membrane functions during phagocytosis.

ACKNOWLEDGMENT

We thank Robert W. Snook II for excellent technical support; Drs P. Beatty and J. Harlan for providing monoclonal antibody 60.3; Drs A. Skubitz, D. Confer, R. Nelson, and J. Eaton for critical review of the manuscript; D. Kamprud for editing; and J. Johnson and M. Berg for preparing the manuscript.

Immunological Specificity and Mechanism of Action of IgG Lupus Anticoagulants

By Vittorio Pengo, Perumal Thiagarajan, Sandor S. Shapiro, and Marilyn J. Heine

Although observations have implied that lupus anticoagulants have immunologic specificity toward anionic phospholipids, this assumption has been directly demonstrated in only one patient with a monoclonal IgM paraprotein. We tested the generality of this hypothesis directly by isolating five IgG lupus anticoagulants from patients with lupuslike syndromes and/or thrombosis. IgG lupus anticoagulant fractions were isolated free of other plasma proteins and free of contaminating phospholipid by adsorption to and elution from cardiolipin-cholesterol-dicetyl phosphate liposomes, followed by chromatography on protein A-Sepharose. Cardiolipin liposomes, but not phosphatidylcholine liposomes, were capable of removing all, or nearly all, lupus anticoagulant activity from patient plasma. The affinity-purified IgG preparations reacted with cardiolipin,

phosphatidylserine, phosphatidylinositol, and phosphatidic acid, but not with phosphatidylcholine or phosphatidylethanolamine, and inhibited calcium-dependent binding of prothrombin and of factor X to phosphatidylserine-coated and to cardiolipin-coated surfaces. F(ab')₂ fragments retained lupus anticoagulant activity and bound to cardiolipin in an enzyme-linked immunosorbent assay (ELISA). Anticardiolipin and lupus anticoagulant activity were both present in acidic fractions on isoelectric focusing. These data strongly suggest that most, if not all, lupus anticoagulants are antibodies that have immunologic specificity towards anionic phospholipids, thereby blocking the calcium-mediated binding of vitamin K-dependent coagulation factors to coagulation-active phospholipid surfaces.

© 1987 by Grune & Stratton, Inc.

LUPUS ANTICOAGULANTS are acquired inhibitors of coagulation tests that occur in systemic lupus erythematosus (SLE), in various other clinical settings, and in apparently normal persons.¹

Because the lupus anticoagulant effect is noted in all phospholipid-dependent coagulation tests²⁻⁶ and because of the correlation between the presence of lupus anticoagulants and reactivity against cardiolipin in solid-phase immunoassays,⁷⁻¹¹ lupus anticoagulants have been widely assumed to be antibodies reactive against anionic phospholipids. Actually, the immunologic nature and mechanism of action of the lupus anticoagulant effect have only been demonstrated in one patient.¹² In 1980, our laboratory¹² clarified the mechanism of action of an IgM λ paraprotein with lupus anticoagulant activity. The purified paraprotein showed immunologic reactivity against the anionic phospholipids phosphatidylserine, phosphatidylinositol, and phosphatidic acid, but did not react with the neutral phospholipids phosphatidylcholine or phosphatidylethanolamine. This protein inhibited the binding of prothrombin and factor X to phospholipid micelles, thereby accounting for the prolongation of phospholipid-dependent coagulation tests.

Since this initial work, it has been widely assumed, although not rigorously demonstrated, that all lupus anticoagulant activity is due to the same mechanism. However, other authors have stressed the heterogeneity of the lupus anticoagulant patient population, as well as the apparent variability in the response of lupus anticoagulant tests to the presence of platelets,¹³ to argue against a common mechanism of action. Interestingly, neither the original patient, nor four other IgM lupus anticoagulants we subsequently studied, nor IgM lupus anticoagulants reported by others,^{14,15} have been associated with thrombosis. Most lupus anticoagulants, on the other hand, occur in a setting of polyclonal increases in immunoglobulins and are associated with a high incidence of thrombosis.^{1,16-21} To assess whether there is indeed a general mechanism for the lupus anticoagulant effect, a technique for isolating lupus anticoagulants from plasma of patients without monoclonal paraproteins is necessary. The preparation must be a pure immunoglobulin free of contaminating phospholipid. We developed a technique that

uses affinity purification on cardiolipin liposomes followed by protein A-Sepharose chromatography to prepare phospholipid-free purified lupus anticoagulants. We isolated five IgG lupus anticoagulants, four from patients with a history of thrombosis, and examined the immunologic nature of their interaction with phospholipids and the mechanism of their inhibition of phospholipid-dependent coagulation tests.

MATERIALS AND METHODS

Human thrombin was a gift from Dr John Fenton, New York State Department of Health Laboratories, Albany. Pepsin was purchased from Worthington Biochemical, Freehold, NJ. Protein A-Sepharose, Sephacryl G-75 (Superfine) and Sephacryl S-300 were obtained from Pharmacia Fine Chemicals, Piscataway, NJ. Ampholines were purchased from LKB, Bromma, Sweden. Phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, phosphatidic acid, and phosphatidylcholine were obtained from Supelco, Bellefonte, PA. Cardiolipin, dicetyl phosphate, cholesterol, alkaline phosphatase-labeled goat antibodies to human IgG, human IgM, and rabbit IgG, as well as *p*-nitrophenyl phosphate and bovine serum albumin (BSA) (fraction V) were purchased from Sigma Chemical, St Louis. The purity of phospholipids was checked by thin-layer chromatography.²² Russell viper venom was obtained from Burroughs Wellcome, Raleigh, NC, and Thrombofax was purchased from Ortho Diagnostic Systems, Raritan, NJ. Antisera to human IgG, IgA, and IgM were obtained from Meloy Laboratories,

Springfield, VA. Standard laboratory chemicals were supplied by Fisher Scientific, Fair Lawn, NJ. Carrier-free ^{125}I was obtained from Cambridge Nuclear, Billerica, MA.

IgG Purification

Lupus anticoagulant plasma was clotted by incubation with 2 U/mL of human thrombin for 2 hours at 37°. Fibrin was removed by centrifugation at 4°C for 10 minutes at 14,000 g. γ -Globulins were precipitated from the supernatant serum by addition at 4°C of an equal volume of saturated ammonium sulphate. After 25 minutes of stirring, the precipitate was recovered by centrifugation in the cold for 10 minutes at 14,000 g. The precipitate was dissolved in approximately one-seventh the original plasma volume, using Tris-buffered saline (TBS: 0.02 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4), and applied to a 2.5×90 -cm column of Sephacryl S-300 equilibrated with TBS. Fractions of 2.5 mL were collected and tested qualitatively for IgG, IgM, and IgA by Ouchterlony double diffusion and for lupus anticoagulant activity by their ability to prolong the dilute Russell viper venom time (RVVT) of normal plasma.^{23,24} Fractions containing lupus anticoagulant activity were pooled and applied to a 1×5 -cm column of protein A-Sepharose equilibrated with TBS. The lupus anticoagulant activity, in every case, was retained on the column and was eluted using a buffer consisting of 0.1 mol/L of glycine, 0.5 mol/L of NaCl, pH 3, and immediately neutralized with 1 mol/L of Tris buffer, pH 8.4. Eluates were dialyzed against TBS before being tested for lupus anticoagulant activity. Control IgG was prepared from normal plasma in an identical manner. IgG prepared in this manner is free of other immunoglobulins and shows no bands other than IgG on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) after staining with Coomassie blue.

F(ab')₂ Preparation

After dialysis against acetate buffer (0.2 mol/L of Na acetate, 0.2 mol/L of NaCl, pH 4), purified IgG (2 to 3 mg/mL) was incubated at 37°C for 20 hours with freshly prepared pepsin at a weight ratio of 50:1.²⁵ At the end of the 20-hour incubation, no intact IgG was detectable by SDS-PAGE. The reaction was stopped by adding solid Tris (5 to 10 mg). The digested material was dialyzed against TBS and applied to a 1×5 -cm protein A-Sepharose column. The flowthrough, containing the F(ab')₂ fragments, was concentrated by Amicon ultrafiltration using PM-10 membranes (Amicon, Lexington, MA) and tested for lupus anticoagulant and anticardiolipin activities. The protein A-Sepharose flowthrough was free of whole IgG and Fc-fragments, as judged by SDS-PAGE and by double diffusion against antiserum to human IgG (Fc-specific).

ELISA for Anticardiolipin Antibodies

One microgram of cardiolipin in 25 μL of ethanol was added to each well of a 96-well microtiter plate (Falcon #3911, Becton Dickinson, Oxnard, CA) and evaporated under a stream of nitrogen for 20 minutes, after which the wells were washed twice with 100 μL of phosphate-buffered saline (PBS: 8 g/L of NaCl, 0.2 g/L of KH_2PO_4 , 2.9 g/L of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 0.2 g/L of KCl, pH 7.4). All subsequent steps were carried out at room temperature. One hundred microliters of 10% fetal calf serum (FCS) in PBS was then added to each well and incubated for 2 hours to block nonspecific binding. After the plates were washed six times with PBS, 100 μL of plasma diluted in PBS containing 10% FCS was added to each well and incubated for 1 hour. The wells were washed six times with PBS, after which 100 μL of a 1:1000 dilution of alkaline phosphatase-labeled goat anti-human IgG or goat anti-human IgM was added and incubated for 1 hour. The plates were then washed six times more in PBS, and 100 μL of freshly prepared *p*-nitrophenyl phos-

phate solution (1 mg/mL in 10% diethanolamine buffer, pH 9.8) was added to each well. After 1-hour incubation, the absorbance was measured at 405 nm, using a Titertek Multiscan plate reader (Flow Laboratories, McLean, VA). In experiments using F(ab')₂, 100 μL of a 1:400 dilution of rabbit anti-human F(ab')₂ (Jackson Laboratories, Avondale, PA) was used as a second antibody, and alkaline phosphatase-labeled goat anti-rabbit IgG was used as the developing antibody.

The ELISA assay for antibody activity against other phospholipids was performed in a similar manner, except that: (a) Two micrograms of phosphatidylserine, phosphatidylinositol, phosphatidic acid, phosphatidylethanolamine, or phosphatidylcholine in 10 μL of chloroform was added to each well of a 96-well microtiter plate containing 30 μL of ethanol; (b) when phospholipid reactivity of eluates from cardiolipin liposomes was studied, 100 μL -aliquots of eluate were used; and (c) the reaction was stopped after 15 minutes.

Isoelectric Focusing

Forty grams of Sephadex G-75 was washed and prepared as described by the manufacturer, and finally suspended in 90 mL of deionized water. To the Sephadex was added: 2.5 mL of Ampholine, pH 5 to 7; 2.5 mL of Ampholine, pH 7 to 9; and 5 mL of purified patient IgG (10 mg/mL in 1% glycine). After gentle stirring, the mixture was poured into a 10×20 -cm glass tray, and excess water was evaporated under a stream of air. Focusing was performed at 10° for 15 hours at 8 W constant power. The gel was then cut into six fractions. A small amount of each fraction was resuspended in deionized water for pH measurement; the remainder of each fraction was resuspended in 5 mL of TBS in a small column, and the proteins were eluted by washing the column with 5 mL of TBS. Column eluates were dialyzed against TBS and tested for lupus anticoagulant and anticardiolipin activities.

Analytical isoelectric focusing was performed in an LKB Multiphor apparatus on 5% polyacrylamide gels containing 2.2% (wt/vol) Ampholine, pH 5.5 to 8.5. Purified IgG or liposome eluates were dialyzed against deionized water, applied to the gel, and run at 50 mA with a constant power of 25 W. The gels were fixed for 1 hour in a solution of 5% trichloroacetic acid and 5% sulfosalicylic acid and stained using the Bio-Rad silver-staining kit (Bio-Rad Laboratories, Richmond, CA).

Immunoaffinity Purification of Anticardiolipin Antibodies

Liposomes were prepared essentially according to the method of Kinsky.²⁶ A mixture of cardiolipin, cholesterol and dicetyl phosphate (molar ratio 10:15:2) in chloroform was dried in a stream of nitrogen in a 25-mL glass tube. The lipids were resuspended in 1 mL of 0.15 mol/L of NaCl by vigorous agitation, using a vortex mixer. After resuspension, the concentration of phospholipids was 5.3 to 5.9 mg/mL. Ten milliliters each of saline and plasma were added to 1 mL of liposome suspension, and the mixture was incubated at 4°C for 30 minutes. After centrifugation at 27,000 g for 10 minutes at 4°C, the precipitate was washed three times with 0.15 mol/L of NaCl. The precipitate was resuspended by vigorous agitation in 2 mL of 3 mol/L of NaCl, following which the suspension was added to a separatory funnel containing 10 mL of ethyl ether.²⁷ After settling, the clear aqueous layer was removed from the bottom of the funnel, centrifuged, and dialyzed in the cold against three changes of TBS. The dialyzed eluate was tested for lupus anticoagulant activity by the dilute RVVT, for immunoglobulin class by Ouchterlony double diffusion, and for reactivity against phospholipids by enzyme-linked immunosorbent assay (ELISA). The eluate was further purified by protein A-Sepharose column chromatography, as previously described, and retested for purity and for biological activities.

Labeling of Cardiolipin with ^{125}I

Cardiolipin was radioiodinated directly by the chloramine-T method, as described by Antonov and colleagues.²⁸ Thin-layer chromatography demonstrated that ~60% of the added radioactivity had been incorporated into cardiolipin. Most of the remainder traveled with the solvent front. Labeled cardiolipin had the same mobility as standard cardiolipin. The spot containing the radioactive cardiolipin was extracted from the silica gel plate as described previously.²² When re-run on thin-layer chromatography, this extracted labeled material showed a single spot with the mobility of standard cardiolipin; no radioactivity was present in the solvent front. On the basis of phosphorus content,²⁹ the specific radioactivity of ^{125}I -cardiolipin was calculated as 26 mCi/mmol.

Coagulation Studies and Assessment of Lupus Anticoagulant Activity

Venous blood was collected in one-tenth volume of 3.8% trisodium citrate, and plasma was obtained by centrifugation in the cold at 2,300 g for 15 minutes. Routine coagulation studies were performed as previously described.¹² Lupus anticoagulant activity of patient plasma was assessed by the dilute RVVT, as previously described.^{23,24} In our laboratory, the dilute RVVT of normal plasma is 25.6 ± 2.6 seconds (± 2 SD). Patients were not considered to have lupus anticoagulants unless their dilute RVVT was >30 seconds and was not corrected by addition of an equal volume of normal plasma. The anticoagulant activity of IgG or of F(ab')_2 was measured in the dilute RVVT by adding 200 μL of the dialyzed test material, instead of the usual 100 μL , to this system. Addition of 200 μL of TBS alone to normal plasma gives a dilute RVVT of 27 to 30 seconds.

Prothrombin and Factor X Binding to Phospholipid

Prothrombin was purified from normal plasma by a slight modification³⁰ of the method of Morrison and Esneuf,³¹ and labeled with ^{125}I by the Iodogen method³² to a specific activity of 231 Ci/mmol. Factor X was purified according to the method of Miletich and co-workers,³³ with some modifications described previously,¹² and labeled with ^{125}I by the Iodogen method to a specific activity of 60 Ci/mmol. Two micrograms of phospholipid was added to each well of a microtiter plate and dried and washed as described above. Two hundred microliters of TBS containing 1 mg/mL of BSA was then added, to block nonspecific binding, and the plates were incubated for 1 hour. After plates were washed once with TBS, 150 μL of TBS containing 1 mg/mL of BSA and 2 mmol/L of calcium was added, followed immediately by 50 μL of immunoaffinity-purified IgG (134 $\mu\text{g/mL}$) or control IgG (150 $\mu\text{g/mL}$) in TBS. The plates were incubated for 1 hour at room temperature, after which 10 μL of labeled prothrombin (1.4×10^6 cpm) or factor X (1.7×10^6 cpm) was added. After 10-minute incubation at room temperature, the wells were aspirated dry, and the bottoms of the wells were punched out and counted in an Isodyne γ -counter (Model 1185, G.D. Searle, Chicago). Maximum binding of prothrombin was determined by addition of TBS-albumin-calcium buffer alone, in the absence of any IgG. As a control, prothrombin and factor X binding were measured in the presence of 2 mmol/L of EDTA and were 3% and 11% of maximum binding, respectively. Residual binding, measured in the presence of a 50-fold excess of cold prothrombin or factor X, was subtracted from total binding, to give "specific" binding.

Patients

Patient no. 1. The patient was a 35-year-old man with a 10-year history of a manic-depressive illness for which he had been treated with lithium, chlorpromazine, and other tricyclic antidepressants. He had not received any medication except lithium in the 6 months

prior to study. He had had several episodes of deep vein thrombosis as well as at least one probable pulmonary embolism. He had a normal platelet count, and his serological test for syphilis (RPR) was negative. At the time of the study, he was receiving warfarin.

Patient no. 2. The patient was a 39-year-old woman with SLE of 8-year duration who had end-stage renal disease and was on hemodialysis. She had had a cerebrovascular accident at the age of 35, and also had a history of possible pulmonary emboli. She had occlusion of arteriovenous shunts in the forearm on at least two occasions. Her platelet count was in the low-normal range. She had a false-positive serological test for syphilis (RPR) at the time of diagnosis, but not at the time of study, when she was receiving 20 mg of prednisone every other day.

Patient no. 3. The patient was a 32-year-old woman with a history of three spontaneous abortions, after which she delivered a full-term live baby while on steroid therapy. She had a normal platelet count. She had had a false-positive serology (RPR) since her teens, but had no other signs of SLE.

Patient no. 4. The patient was a 49-year-old man with a 10-year history of SLE. He had an acute episode of right ileofemoral arterial occlusion 1 year earlier, at which time a lupus anticoagulant was discovered. He had a normal platelet count and a negative serological test for syphilis (RPR).

Patient no. 5. The patient was a 58-year-old woman with renal disease and possible SLE. She had no history of thromboembolic phenomena. She had a normal platelet count and a false-positive serology (RPR). At the time of the study, she was receiving 20 mg of prednisone daily.

As shown in Table 1, all five patients had a prolonged dilute RVVT, which did not normalize on addition of an equal volume of normal plasma. Four of the five patients had a prolonged activated partial thromboplastin time (APTT), whereas only one (patient no. 1, receiving warfarin) had a prolonged prothrombin time (PT).

RESULTS

Immunoglobulin Nature of the Lupus Anticoagulant and Anticardiolipin Activities

Lupus anticoagulant activity in all five patients gel-filtered on Sephacryl S-300 in the IgG peak. Three patients (patients no. 1, 3, and 5) had, in addition, a very small amount of inhibitory activity associated with the IgM peak. The maximum prolongation of the dilute RVVT in IgM fractions was 2 seconds, whereas the maximum prolongation in the IgG peak was 13 to 14 seconds. No prolongation of the RVVT was observed in any of the Sephacryl S-300 fractions of control plasma. The IgG peaks were further purified by chromatography on protein A-Sepharose. Glycine eluates of the protein A-Sepharose columns contained the inhibitory activity, whereas the flowthrough fractions had no lupus anticoagulant activity.

IgG anticardiolipin activity was detected in all five patient

Table 1. Screening Coagulation Tests

	Patient					Normal
	1	2	3	4	5	
APTT (s)	90.0	27.0	42.6	38.4	42.0	23-36
PT (s)	23.2	11.7	13.2	12.2	12.0	11.5-13.5
Dilute RVVT (s)						
Patient	38.2	33.4	34.0	36.5	46.3	23-28.2
Patient + normal (1:1)	36.6	30.4	29.9	32.0	42.7	23-28.2

plasmas; in addition, patients 1, 3, and 5 had weak IgM anticardiolipin activity.

F(ab')₂ fragments prepared from patient IgG prolonged the dilute RVVT of normal plasma in a dose-dependent manner; normal F(ab')₂ had only a minimal effect on this test (Fig 1A). Patient F(ab')₂ fragments also bound in a dose-dependent manner to cardiolipin in the ELISA, whereas control F(ab')₂ showed only minimal binding (Fig 1B).

Preparative isoelectric focusing of purified IgG from patient 1 (Fig 2) demonstrated a peak of lupus anticoagulant and anticardiolipin activity in the first fraction, pH 5.8; in contrast, IgG was distributed throughout all six fractions relatively equally.

Immunoaffinity Purification and Properties of Lupus Anticoagulant and Anticardiolipin Antibodies

As shown in Table 2, when IgG-containing fractions from a Sephacryl S-300 column (patient no. 5) were incubated with cardiolipin liposomes, nearly all lupus anticoagulant activity was adsorbed. When phosphatidylcholine liposomes were used instead, no lupus anticoagulant activity was

Fig 1. (A) Effect of F(ab')₂ fragments and whole IgG on the dilute RVVT of normal plasma. Control F(ab')₂, ●—●; patient F(ab')₂, ●—●; patient IgG, ▲—▲. Patients are identified by number. (B) Anticardiolipin activity of F(ab')₂ fragments.

Fig 2. Preparative isoelectric focusing on Sephadex G-75 of IgG from patient no. 1, purified on protein A-Sepharose.

adsorbed. The cardiolipin liposome eluate contained lupus anticoagulant activity, whereas the phosphatidylcholine liposome eluate contained none.

Cardiolipin liposome eluates were prepared from patient and normal plasmas (Table 3). Eluates from patient plasma, in contrast to eluates from normal plasma, possessed lupus anticoagulant activity. When tested by Ouchterlony double diffusion, patient eluates contained IgG and albumin, whereas control eluates contained only albumin. Patient and control eluates were negative for IgM, IgA, and lipoproteins by the same method. Final purification of patient liposome eluates was achieved by chromatography on protein A-Sepharose. Eluates from this column were pure IgG preparations, as judged by double diffusion and by silver staining of SDS-PAGE gels. To estimate the cardiolipin contamination of the affinity-purified IgG, we purified one patient plasma with liposomes containing ¹²⁵I-cardiolipin. The starting liposome preparation contained 216,250 cpm. The centrifuged, dialyzed liposome eluate contained 219 cpm. After protein A-Sepharose chromatography, the eluted IgG contained only 42 cpm, representing <1 mol of cardiolipin/10¹⁰ mol of IgG.

The affinity-purified antibodies prolonged the dilute RVVT of normal plasma in a dose-dependent manner, as shown in Fig 3. A final concentration of as little as 3.3 μg/mL of this purified antibody produced a measurable increase in the clotting time. Control IgG had no effect. Based on the anticoagulant activity of the affinity-purified IgG, we estimate that lupus anticoagulants in these patients account for no more than 0.2% of the total plasma IgG.

Table 2. Specificity of Liposome Purification

Test Material	Dilute RVVT (s)
Sephacryl S-300 IgG pool	38.5
Liposome eluate*	
Cardiolipin	42.3
Phosphatidylcholine	29.9
Liposome supernatant*	
Cardiolipin	31.7
Phosphatidylcholine	41.1
Buffer	28.8

*After protein A-Sepharose chromatography.

Table 3. Lupus Anticoagulant Activity of Liposome Eluates From Patient and Normal Plasma

Patient	A ₂₈₀ Eluate	Dilute RVVT (Eluate/Buffer, s)
1	0.237	34.4/27.9
2	0.991	38.8/27.9
3	0.291	36.9/28.4
A	0.044	26.9/27.8
B	0.114	29.4/28.4

With the ELISA test system, the cardiolipin liposome eluates reacted with cardiolipin and, as shown for patient 1 in Fig 4, also reacted with phosphatidylserine, phosphatidylinositol, and phosphatidic acid, but not with phosphatidylethanolamine, phosphatidylcholine, or dicetyl phosphate. Identical results were obtained in all four patients tested (patients no. 1, 2, 3, and 5). Normal IgG, at approximately the same concentration as in patient eluates, showed no reactivity against any phospholipids. In addition, liposome eluates from normal plasma contained only trace amounts of protein and showed little or no reactivity.

Analytical isoelectric focusing of affinity-purified, phospholipid-free IgG from patients no. 2 and 3 (Fig 5) showed several bands of acidic pI; in contrast, the bulk of normal IgG focused in the alkaline range.

Inhibition of Prothrombin and Factor X Binding to Phosphatidylserine-coated Surfaces

The calcium ion-dependent binding of ¹²⁵I-prothrombin to phospholipid-coated surfaces was studied in microtiter plates. As expected, prothrombin bound to phosphatidylserine-coated wells (136 to 205 fmol/well, in eight experiments), and, to a much lesser extent, to cardiolipin-coated wells (27 and 44 fmol/well, in two experiments). In contrast, prothrombin binding to phosphatidylcholine-coated wells was only 6.2 and 7.0 fmol/well in two experiments, a figure similar to the value obtained for nonspecific binding to phosphatidylserine-coated wells in the presence of EDTA (6 to 9 fmol/well). As shown in Fig 6A, immunoaffinity-purified patient IgG inhibited the binding of prothrombin to phosphatidylserine-coated wells by 73% and 66%, respec-

Fig 3. Effect of affinity-purified patient IgG and control IgG on the dilute Russell viper venom time (RVVT) of normal plasma.

Fig 4. Antiphospholipid activity (ELISA) of cardiolipin liposome eluates. Because control eluates contained essentially no IgG, reactivity of purified normal IgG is also shown.

tively. Purified IgG from patient no. 1 (not shown in Fig 6), tested only at a much lower protein concentration (23 µg/mL), inhibited prothrombin binding by 25.5%. Binding of factor X was also inhibited by patient IgG, although to a slightly lesser extent than prothrombin (Fig 6B). Three control IgG preparations showed no inhibition of prothrombin or factor X binding. Binding to cardiolipin-coated wells was also inhibited by patient eluates.

DISCUSSION

Although earlier observations implied that lupus anticoagulants have as their locus of action the negatively charged phospholipids,^{1,3,5,6,34} this assumption has been directly demonstrated in only one patient.¹² On the basis of this case, the correlation that has been observed between the presence of anticardiolipin activity and lupus anticoagulant activity,⁷⁻¹¹ as well as some more recently described absorption studies,³⁵ all lupus anticoagulants have been widely assumed to operate by the same mechanism. We tested the generality of this hypothesis directly in five patients with lupuslike syndromes and/or thrombosis, whose lupus anticoagulants were largely IgG.

Fig 5. Analytical isoelectric focusing of normal IgG (lane 1) and immunoaffinity-purified IgG from patients no. 2 and 5 (lanes 2 and 3).

Fig 6. Effect of affinity-purified antibodies on binding of ^{125}I -prothrombin (A) and ^{125}I -factor X (B) to phosphatidylserine-coated wells. Patients are identified by number. Controls are purified normal IgG at the same concentration as affinity-purified patient IgG.

We demonstrated that both lupus anticoagulant and anticardiolipin activities are mediated by the F(ab')_2 portion of IgG and therefore are immunologic in nature. We demonstrated that all, or nearly all, lupus anticoagulant activity can be adsorbed on cardiolipin-containing liposomes, but not on phosphatidylcholine-containing liposomes. We further demonstrated that with a combination of cardiolipin-liposome adsorption, high molarity NaCl and ether elution, and protein A-Sepharose chromatography, it is possible to obtain pure, phospholipid-free, IgG fractions from patient plasma that interact with anionic but not neutral phospholipids and also act as lupus anticoagulants. Recently, Harris and associates¹¹ reported a cardiolipin liposome purification procedure using 1 mol/L of sodium iodide as the elutant. We previously used sodium iodide as an elutant from phosphatidic acid³⁶ and phosphatidylserine³⁷ liposomes, but found that these preparations were heavily contaminated with phospholipid, making some subsequent testing procedures difficult to evaluate. For example, the presence of free and IgG-bound phospholipid in the liposome eluates interfered with coagulation tests and was capable of producing spurious results on isoelectric focusing. For this reason, we developed the present liposome elution procedure. In addition, since

cardiolipin liposome eluates invariably contain significant amounts of albumin, a further purification step by protein A-Sepharose chromatography was added.

Using these preparations, we were able to obtain a good dose-response relationship between lupus anticoagulant activity and IgG concentration and to detect lupus anticoagulant activity at IgG concentrations as low as 3 $\mu\text{g/mL}$. Thus, the dilute RVVT, as normally performed on plasma, can detect lupus anticoagulants at plasma concentrations of $\geq 10 \mu\text{g/mL}$.

The mechanism of prolongation of phospholipid-dependent coagulation tests in the patients we studied is similar to that of the patient previously reported.¹² Our data clearly show inhibition by patient affinity-purified IgG of prothrombin binding to phosphatidylserine surfaces and, to a lesser extent, a similar inhibition of factor X binding. The reason for this difference in inhibition is not presently known. Our data further indicate that prothrombin can bind to cardiolipin surfaces, although to a much lesser extent than to phosphatidylserine surfaces, and that this binding is also inhibited by the affinity-purified IgG.

Although all six lupus anticoagulants we studied in this and the previous¹² report are clearly antibodies with anionic phospholipid specificity, these anticoagulants probably represent only a subpopulation of antibodies to anionic phospholipids. Several studies suggest that there may be more than one type of anticardiolipin antibody,^{10,38-40} and we have studied patients with true-positive and false-positive serologies whose anticardiolipin antibodies did not possess lupus anticoagulant activity. Furthermore, the presence of several distinct bands on isoelectric focusing of the affinity-purified IgG preparations from our patients raises the possibility that not all affinity-purified IgG anticardiolipin antibodies possess lupus anticoagulant activity.

In addition to anticardiolipin antibodies, other phenomena have been correlated with the presence of a lupus anticoagulant, including biologic false-positive serology,^{1,3,40,41} thrombocytopenia,^{7,20} a history of recurrent abortions,⁴²⁻⁵³ and a high incidence of thromboembolic phenomena.^{1-7,42,43} Three of our patients had false-positive serologies, and only 1 may have had thrombocytopenia, whereas 4 of the 5 had either a history of thrombosis or of recurrent abortion. Because this is a highly selected group, no conclusions can be drawn concerning incidence of these clinical findings. Because all patients had anticardiolipin antibodies, it is surprising that two had negative serologies. Even a high concentration (56 $\mu\text{g/mL}$) of affinity-purified IgG from one patient did not produce a positive RPR serology, suggesting that antibody concentration alone may not explain this observation. In this connection, it is of interest that the two patients with positive serologies at the time of our study had some IgM lupus anticoagulant and IgM anticardiolipin activity. Because many flocculation tests are more sensitive to IgM than to IgG antibodies,⁵⁴ a biologic false-positive serology may correlate better with levels of IgM than of IgG anticardiolipin antibodies.

The high correlation between lupus anticoagulants and thrombocytopenia raises the question of the interaction of lupus anticoagulants with platelets. The strong correlation

with thromboembolic phenomena and the possible effect of lupus anticoagulants on endothelial cell prostacyclin production⁴⁷ raise similar questions concerning the interaction of these antibodies with endothelial cells. It will be of interest to determine whether purified lupus anticoagulants interact with platelets or endothelial cells, or whether the clinical phenomena observed depend on other factors.

ACKNOWLEDGMENT

We wish to thank Drs S. Cowchock, R. Zalusky, and N. Jeremovich for providing patient plasma samples; Dr I. Alam for the phosphorus determinations; S. McCord for expert technical assistance; and Eliza Battle and Rosemarie Silvano for typing the manuscript. We also wish to thank Dr S. Cowchock for her assistance in setting up the anticardiolipin ELISA assay.

Cytoplasmic Factor Required for Entry of Malaria Parasites Into RBCs

By K. Rangachari, A.R. Dlugowski, R.J.M. Wilson, and W.B. Gratzer

Resealed ghosts of human RBCs, containing diluted cytosol, are susceptible to invasion by *Plasmodium falciparum*. If ATP is present, a dilution of up to about 30-fold, corresponding to an intracellular hemoglobin concentration of ~10 mg/mL, can be tolerated without total loss of susceptibility to invasion. Up to a dilution of about one-half this, the parasites also develop normally. When the cytosol is diluted by more than the critical amount, invasion of the resulting resealed ghosts falls off abruptly. If the diluent buffer is replaced by extraneous concentrated hemolysate, an indefinite dilution is possible without loss of invasion. There is thus an intracellular constituent, which must be present at a concentration above some critical level if the parasite is to enter the cell. The factor in question is not dialyzable. It is largely inactivated when the hemolysate is kept for ~1 day in the cold or for ~20 minutes at 45°C. The inability of a heat-treated hemolysate to support invasion is not due to the generation of inhibitory products, because such a solution can be used as a diluent of a fresh

hemolysate without inhibition of invasion. When the inactivated hemolysate is present as a major component, however, the parasites fail to develop to the trophozoite stage. The invasion-linked factor remains in the strongly adsorbed nonheme fraction when a batchwise separation from hemoglobin on an anion exchanger is made and is thus probably acidic in character; the adsorbed fraction, recovered from the ion-exchanger, substantially restores capacity for invasion when sealed into ghosts. Its activity is destroyed by treatment with trypsin. The adsorbed fraction contains many proteins. When fractionated on a gel filtration column by fast liquid chromatography, active material eluted at a volume corresponding to a mol wt for a globular protein in the region of 10,000. A component of apparent subunit mol wt of 13,000 was observed in sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of this eluate fraction.

WHITE GHOSTS prepared from simian RBCs do not support invasion by merozoites of *Plasmodium knowlesi*,^{1,2} even though the initial recognition process still appears to operate.¹ It has, however, proved possible to prepare resealed ghosts that are susceptible to invasion by ensuring a sufficient ATP concentration in the internal solution.^{3,4} There are indications that the ATP is required for phosphorylation of membrane-associated proteins, possibly spectrin.⁴ To prepare resealed ghosts, we dialyzed RBCs against a hypotonic medium, including in the solution any solutes to be introduced into the cells; the dialysate is then restored to isotonicity and dialysis is continued at 37° to bring about resealing.² When ATP is present, the hematocrit of the original cell suspension can be reduced to 5% to 10% without eliminating the capacity for invasion of the resulting resealed ghosts; that is, a hemoglobin concentration of <30 mg/mL inside the cell is sufficient to allow invasion and indeed development of the parasites.⁴ However, a dilution is eventually reached at which no invasion will occur. Thus a component in the cytoplasm, other than ATP, is evidently required, the concentration of which must not fall below some critical level, if the membrane is to remain capable of penetration by the merozoite. We report here the results of our attempts to establish the nature of this component.

MATERIALS AND METHODS

P. falciparum was maintained in continuous culture⁵ in adult human RBCs. Schizonts were isolated by a procedure based on that of Saul and colleagues,⁶ involving centrifugation on a cushion of Percoll.⁷

Resealed ghosts, containing 1 mmol/L of magnesium ATP, were prepared as described previously.^{2,4} In brief, washed intact cells were suspended at the required hematocrit in a solution of the required composition and dialysed at 4°C for 2 hours against 100 vol of 5 mmol/L of phosphate buffer, pH 7.4, containing in addition any diffusible solutes present in the suspending solution inside the dialysis bag. The dialysate was then restored to isotonicity (0.15 mol/L of sodium chloride, 5 mmol/L of potassium phosphate), and dialysis was resumed for 45 minutes at 37°C. The resulting resealed ghosts were washed three times in culture medium (RPMI 1640,

containing 10% vol/vol human serum), and were finally suspended at 50% hematocrit in the same solution. The hemoglobin content of the cells was determined by lysing an aliquot after the buffer wash with an equal volume of the 5 mmol/L of phosphate buffer and determining the absorbance at 577 nm, the millimolar absorptivity per heme being taken as 15.2. The Visking dialysis tubing was prepared by boiling in three changes of a solution of 0.1 g/L of sodium bicarbonate and 0.1 mmol/L of EDTA.

Undiluted fresh hemolysate was prepared by freezing and thawing packed washed cells three times and removing stromal material by centrifugation at 42,000 g for 20 minutes. Heat denaturation experiments were carried out by warming the hemolysate in a water bath at the desired temperature for 15 or 20 minutes and clarifying the solution by centrifugation as before. Small volumes were rapidly stripped of dialyzable components on centrifugal columns, packed with Sephadex G-25 in isotonic buffer. The columns (supplied by Pharmacia Fine Chemicals, Uppsala, Sweden) were 10 cm long, and contained ~1.8 mL of Sephadex. After centrifugation of the columns packed with Sephadex at 200 g in a bench-top centrifuge for 2 minutes, 0.1 or 0.2 mL of the hemolysate was applied to each column and brought through by a further centrifugation. Hemoglobin concentrations were determined spectrophotometrically, and ATP was determined by luciferin-luciferase assay,⁸ using an LKB Lumimeter 1250 (LKB Instruments, Bromma, Sweden).

Batch-fractionation of the hemolysate was accomplished on diethylaminoethanol (DE) 52 cellulose (Whatman, Maidstone, UK) following the general procedure of Cheung and colleagues.⁹ The ion-exchanger, equilibrated with 10 mmol/L of sodium phosphate, pH 7.5, was added to a hemolysate (1 g to 5 mL), prepared by lysis of

packed, washed cells with 2 vol ice-cold water, followed by centrifugation at 42,000 g for 20 minutes to remove stroma. The mixture was gently stirred for 30 minutes at 4°C and centrifuged at low speed. The supernatant, containing the hemoglobin, was removed, and the cellulose was washed with 5 mmol/L of phosphate buffer, pH 7.4. The adsorbed protein was liberated from the cellulose by addition of potassium chloride 1 mL of 0.5 mol/L/g of cellulose, followed by stirring for 1 hour on ice. The supernatant was collected after brief centrifugation and concentrated by passage through a centrifuge tube packed with dry Sephadex G-25.¹⁰ It was finally reequilibrated with isotonic phosphate-buffered saline (PBS), using the centrifugal Sephadex column, as above. A nominal protein concentration was obtained by the method of Bradford,¹¹ and was generally ~1 mg/mL. This preparation could be stored frozen for some days without loss of activity.

A hemoglobin preparation, free of most minor cytoplasmic proteins, was also prepared by chromatography of centrifuged hemolysate on a column (2.5 × 90 cm) of Sephadex G-75.

To examine the effect of proteolysis, trypsin (10 µg/mL final concentration) was added to the solution of nonheme protein, prepared as above. After 5 minutes at 37°, soyabean trypsin inhibitor was added from a stock solution to give a final concentration of 100 µg/mL. As a control, samples were treated with a mixture of trypsin and trypsin inhibitor in the same final proportions.

The first attempt at further fractionation of the active nonheme hemolysate fraction made use of a triacetate ultrafiltration membrane (Sartorius Centrisart; Sartorius, Göttingen, FRG) with a nominal mol-wt cut-off of 20,000. To characterize and isolate the active material, fast liquid chromatography (Pharmacia FPLC) was used, with two Superose 12 columns (1 × 50 cm) in series. Samples of 0.5 mL were applied, and the columns were eluted with PBS, pH 7.4, at a flow rate of 0.7 mL/min. The column was calibrated with the following proteins as mol-wt markers: β -galactosidase, human immunoglobulin G, transferrin, bovine serum albumin (BSA), ovalbumin, trypsinogen, bovine β -lactoglobulin, soy bean trypsin inhibitor, bovine pancreatic ribonuclease, horse heart cytochrome c, and bovine pancreatic trypsin inhibitor. Potassium nitrate was used as a marker for the included volume, and blue dextran (Pharmacia) was used for the void volume. Fractions of 1.5 mL were collected and stored frozen. The fractions were concentrated to 0.3 to 0.4 mL with dry Sephadex G-25, as described. For invasion assays, the material was incorporated into resealed ghosts: the hematocrit was chosen to give a low basal invasion level (Fig 1). Thus, lysis and resealing was done in a mixture containing 12 µL of packed cells (sampled with a positive-displacement pipette), 10 µL of 20 mmol/L of magnesium ATP, 100 µL of the concentrated fraction, made up to 200 µL with buffer; three or four replicate assays were performed on each fraction.

Gel electrophoresis with sodium dodecyl sulfate (SDS) was performed in vertical polyacrylamide slab gels in the system of Swank and Munkres,¹² which gives good resolution in the low-mol-wt range. The gels were stained with Coomassie brilliant blue or silver.¹³ Experiments were also performed with resealed ghosts containing added enzymes, ie, glyceraldehyde 3-phosphate dehydrogenase, glucose 6-phosphate dehydrogenase, aldolase, phosphofructokinase, catalase, carbonic anhydrase, and superoxide dismutase (Sigma Chemicals, St Louis). These were added to the suspending solution before reversible lysis at the concentration corresponding to that present in the normal RBC.¹⁴

For invasion assays, purified schizonts (80% to 90% purity) were added to the RBC or ghost suspension; after incubation, parasitemia levels were determined by counting 10³ cells on thin smears, stained with Giemsa's solution. Invasion efficiency is expressed in terms of the invasion ratio,⁴ which is defined as the ratio of the proportion of

Fig 1. Invasion of resealed ghosts (average of seven experiments), containing the original cytosol, diluted as indicated with isotonic saline buffer (○) and with a fresh hemolysate (●); 1 mmol/L of ATP was present throughout. The controls (100%) were resealed ghosts containing the fresh hemolysate, diluted with an equal volume of buffer, giving an average invasion ratio of 2.2. The point at highest dilution corresponds to a 64-fold dilution (volume fraction of diluent 0.984).

parasitized cells at a given time to that at the time of inoculation (0 hours).

RESULTS

Figure 1 shows the dependence of invasion by merozoites on the dilution of the cell contents. ATP at 1 mmol/L, added as the magnesium salt, was present throughout. There was no major or consistent effect of 2,3-diphosphoglycerate or glutathione (GSH) on the invasion levels, although occasionally (presumably when some oxidation of membrane protein thiol groups had occurred) glutathione increased invasion perceptibly (data not shown). The profile of Fig 1 shows a rather abrupt decline of invasion at a critical dilution of the hemolysate, which varied somewhat from preparation to preparation, but always fell to zero at 20- to 50-fold. In the experiment shown (Figs 1 and 2), there was still detectable invasion at 30-fold dilution (97% diluent buffer in Fig 1), corresponding to an intracellular hemoglobin concentration of ~10 mg/mL. Under these conditions, the staining of the cytosol is so weak that phase contrast is required to see the cells clearly. At a 16-fold dilution (hemoglobin concentration ~20 mg/mL), the parasites continued to develop, and ring forms could be observed, whereas at higher dilution there was little indication of maturation (Fig 2).

The implication of the profile of invasion against dilution, seen in Fig 1, is that a cytosolic component other than ATP, diphosphoglycerate, or glutathione is required for invasion and that its concentration must exceed ~1/30 of its normal concentration in the circulating RBC. This factor may bind to the membrane and be progressively dissociated on dilution. To confirm that an intracellular factor exists, and that the decline of the capacity for invasion is not due to an irreversible change in the membrane, resulting from dilution, the same experiment was made with concentrated freshly prepared hemolysate in place of isotonic buffer. A dilution of

Fig 2. Infected resealed ghosts, viewed in phase contrast (original magnification $\times 1,500$; current magnification, $\times 1,000$). R, rings; T, trophozoites. (A) Ghost contents are cytosol diluted 16-fold with isotonic buffer (hemoglobin concentration ~ 20 mg/mL), 21 hours after inoculation; (B) the same 45 hours after inoculation; (C) ghost contents are cytosol diluted by a factor of 32 (hemoglobin concentration ~ 10 mg/mL) 21 hours after inoculation; (D) the same 45 hours after inoculation. Trophozoites are poorly developed in (D) as compared with (B).

1:1 of the fresh hemolysate (prepared by freezing and thawing of packed cells, followed by centrifugal removal of stromal material) was selected, being more effective in promoting invasion than the undiluted hemolysate. The results of such an experiment are shown in Fig 1, from which it is clear that there is no longer any decline of invasion at some critical dilution of the membranes during lysis and resealing. Thus, an essential constituent for invasion is indeed present in the cytosol. The slightly lower basal level of invasion when undiluted hemolysate was used was always observed and remains unexplained; we conjecture that it may be related to the effect of internal viscosity on the membrane properties.¹⁵

To establish whether the unknown component is a dialyzable factor or a macromolecule, the hemolysate was dialyzed for 24 hours against isotonic buffer containing 1 mmol/L of ATP. When this was used in a lysis and resealing experiment, the resulting cells were poorly invaded. However, a comparable loss of invasion capacity occurred when the hemolysate was simply allowed to stand at 4°C for a similar period. Thus, the factor in vitro is substantially inactivated within ~ 1 day in the cold. The activity could not be restored with 1 mmol/L of glutathione. A rapid method for removal of dialyzable solutes was therefore used. Small centrifugal columns packed with Sephadex G-25 proved satisfactory. About 100

μL of fresh concentrated hemolysate could be applied to each, and the hemoglobin was recovered, diluted by not more than 25%. As judged by analysis of the ATP content of the fresh hemolysate and the centrifugal eluant, removal of ATP and, by implication, of other dialyzable solutes, was complete. This procedure required only a few minutes. The resulting stripped hemolysate retained most of its capacity to restore the invasion of resealed ghosts (Table 1). We infer that the factor is macromolecular.

If the molecule in question is a protein, and is inactivated on standing in the cold, one might expect that it would be sensitive to denaturation generally. The hemolysate was therefore subjected to heat treatment. With increasing temperature, appreciable turbidity was apparent in the solution after dilution for spectrophotometry. Moreover, ghosts resealed with hemolysate, which had been treated at $\geq 50^{\circ}$ for 15 minutes and centrifuged, separated into two layers after sealing, the lower one darker than the upper. Thus, at high temperature, complicating factors arise. However, inactivation of the hemolysate, with respect to its capacity to restore susceptibility to invasion of sealed ghosts, was largely complete after heating at 45° for 15 minutes (Fig 3, inset). Under these circumstances the hemoglobin was undamaged, as judged by its absorption spectrum, which was that of oxyhemoglobin, both in the visible and Soret regions, with no

Table 1. Invasion of Resealed Ghosts Containing Different Hemolysate Fractions

Contents of Ghosts*	Invasion Ratio†	No. of Experiments	Key in Fig 4‡
Dilute Cytosol (16-fold dilution with buffer§)	0.29 ± 0.10 (SD)	16	A
Concentrated cytosol (extraneous hemolysate, diluted with equal volume buffer)	2.10 ± 0.93	13	B
Stripped hemolysate (as previous, but after removal of dialyzable solutes)	1.40 ± 0.16	3	
Heated hemolysate (fresh hemolysate, heated at 45°C and diluted with equal volume buffer)	0.73 ± 0.35	7	C
Unadsorbed fraction from DE 52 (diluted with equal volume buffer)	0.47 ± 0.08	6	D
Adsorbed fraction from DE 52 diluted threefold with heat-inactivated hemolysate	2.00 ± 1.1	4	E
Adsorbed fraction from DE 52 diluted threefold with buffer	1.05 ± 0.24	6	F

*RBCs were lysed and resealed at 6% hematocrit in the specified solutions

†Invasion ratio is parasitemia after one invasion cycle (~24 hours) to that at inoculation (starting parasitemias in range 1% to 5%).

‡Data represented as points in Fig 4.

§Phosphate-buffered saline, containing 1 mmol/L of magnesium ATP.

indication of the formation of a hemichrome or of methemoglobin (which would have revealed itself in a reduction in the ratio of intensities of the visible bands at 577 and 542 nm, and in the appearance of a band at longer wavelengths).¹⁶

The fall in invasion could be interpreted in terms of heat-inactivation of the hemolysate or of the formation of a product of heating (possibly aggregated protein)¹⁷ that could damage the membrane. To test this, mixtures of fresh and heated hemolysates, matched for hemoglobin concentration, were made up and assayed for their activity in restoring invasion. Within the limits of experimental error, dilution of fresh with heated hemolysate caused no greater reduction of

invasion than did dilution with isotonic buffer (Fig 3). We thus conclude that the active factor is destroyed by relatively mild heat treatment. A striking feature of these results, however, was that when the proportion of heated hemolysate was substantial, the parasites, though present in the cells in undiminished numbers, failed to develop to the trophozoite stage. Thus, heat treatment either reduced the concentration of a constituent required for parasite maturation to below some critical level or generated a species toxic to the intracellular parasite. Hemoglobin, freed of most cytoplasmic proteins, introduced into ghosts, together with magnesium-ATP, gave almost no invasion (Table 1 and Fig 4D).

We attempted to obtain an active fraction from concentrated fresh hemolysate by a batch separation on the anion exchanger, DE52 cellulose.⁹ The supernatant from this procedure had low activity with respect to restoration of invasion of resealed ghosts, whereas the adsorbed nonheme fraction, recovered from the ion-exchanger, showed significant activity, both when mixed with an inactivated hemolysate or with diluent buffer and then introduced into ghosts (Table 1 and Fig 4E and F).

As a further indication that the active constituent is a protein, samples were exposed to trypsin (10 µg/mL for 5 to 10 minutes); the reaction was terminated by addition of an excess of soy bean trypsin inhibitor. Such treatment reduced the invasion of cells containing the preparation (with or without additional DE52-stripped hemolysate) by 50% to 60%. Controls, treated with a trypsin-trypsin inhibitor mixture, showed no such reduction.

To examine whether any of the common enzymes of the RBC cytosol might be implicated, glyceraldehyde 3-phosphate dehydrogenase, glucose 6-phosphate dehydrogenase, aldolase, phosphofructokinase, catalase, carbonic anhydrase, and superoxidase dismutase were incorporated in the diluent buffer used to prepare resealed ghosts, at concentrations corresponding to those in the native cell.¹⁴ In no case was the efficiency of invasion affected (data not shown).

As a first step toward a characterization of the active factor, the active fraction from the anion exchanger was passed through a centrifugal cut-off filter, with a nominal mol-wt exclusion of 20,000 for globular proteins. The activity was recovered in the filtrate. A protein of low mol wt was thus indicated.

The active hemolysate fraction was applied to a Superose

Fig 3. Invasion ratio (ie, parasitaemia ~24 hours after inoculation, relative to that at time of inoculation) in resealed ghosts, containing fresh hemolysate, diluted with varying proportions of isotonic buffer (○) and with heat-inactivated hemolysate (●) (1 mmol/L of ATP present throughout). Inset: Effect of temperature of heating on activity of a fresh hemolysate with respect to its ability to restore susceptibility of resealed ghosts to invasion. The controls were resealed ghosts, containing a 16-fold dilution of hemolysate that had been incubated at 37°C for 15 minutes.

Fig 4. Summary of data for invasion of resealed ghosts, containing various hemolysate-derived preparations: (A) Sixteen-fold dilution of normal contents; (B) dilution 1:1 of freshly prepared hemolysate; (C) dilution 1:1 of heat-treated hemolysate; (D) inactive fraction of hemolysate, recovered after ion-exchange treatment, and containing the hemoglobin; (E) heat-treated hemolysate with added active fraction, recovered from ion-exchanger; (F) 16-fold dilution of normal contents with added active fraction.

12 gel filtration column in an FPLC apparatus. The column was calibrated with a series of globular proteins (Fig 5, inset). Fractions were assayed for activity in promoting malarial invasion. They were first concentrated about four-fold and added to the buffer in which the resealed ghosts were prepared. A hematocrit of 6% (16-fold dilution of cell contents after lysis and resealing) was selected to give a low basal parasitemia (Fig 1). Not all the elution profile could be assayed, because in each of three experiments several fractions caused the resealed ghosts to become misshapen and vesiculate. The reason for this was not discovered; the effect could not be reversed by the addition of 10 mg/mL of fatty acid-free BSA to adsorb lysolipids, or by inclusion of 0.2 mmol/L of EGTA in the buffers used in the course of the preparation up to the column stage, to exclude calcium ions. Three separate elutions allowed assay of most of the profile: only seven fractions (including the void volume) caused vesiculation in all experiments. An elution curve, with activity assays, is shown in Fig 5. In all experiments, activity was discovered within the elution volume range of 38 to 42 mL. This corresponds to a mol wt for a globular protein of ~10,000, although the curvature of the calibration curve in this region¹⁸ limits the precision of the estimate. As Fig 5 also shows, the protein concentration, as judged by the absorbance at 280 nm in this region of the elution profile, is low. Gel electrophoresis in the presence of SDS revealed a component

Fig 5. Fast protein liquid chromatography elution profile from Superose 12 column of active preparation, recovered from ion-exchanger. Lower panel shows the activities of the fractions in terms of the invasion of resealed ghosts, into which they had been introduced. Unassayed fractions caused distortion or vesiculation of the ghosts. The controls (100%, corresponding to an invasion ratio of 0.4) were ghosts resealed with a 16-fold dilution of hemolysate with isotonic buffer (containing 1 mmol/L of magnesium ATP), to give a low basal invasion efficiency. Inset: Mol-wt calibration of the column.

with an apparent subunit mol wt of ~13,000 and also various weaker bands.

DISCUSSION

Several unexpected features emerged from these studies. First, resealed ghosts, depleted of the bulk of the hemoglobin and other cytosolic contents, are still susceptible to invasion by *P. falciparum*. Second, only ~6% of the hemoglobin concentration (ie, ~20 mg/mL) is required for the intracellular parasites to develop to the schizont stage. This implies that the amount of hemoglobin needed for the metabolic processes of maturation and egress from the cell is much lower than had been supposed (for review, see ref. 19). After a larger (30-fold) dilution, the capacity of the cytosol to support normal maturation of parasites is altered; dilution of the fresh hemolysate with heat-treated hemolysate has a similar effect. The factor required for maturation could well be a host cell enzyme, such as superoxide dismutase, on which the parasite is thought to be dependent.²⁰

The invasion-related factor must be supposed normally to bind to or to modify the membrane enzymically in such a manner as to affect its structure, as perceived by the parasite at the outer surface. Several RBC proteins bind to the membrane cytoskeleton, including glyceraldehyde 3-phosphate dehydrogenase,²¹ phosphoglycerate kinase,²² phosphofructokinase and aldolase,²³ calmodulin,²⁴ and catalase,²⁵ as well as hemoglobin²⁶; tropomyosin is also associated with the actin protofilaments.²⁷ None of the cytosolic enzymes that we

examined was able to restore the capacity of the diluted cytosol to support invasion, however. In all these cases, dilution, as well as such factors as calcium²⁵ and magnesium²⁶ concentration, may be expected to change grossly the amount of the component bound to the membrane. Whether, and in what manner, different cytoplasmic proteins might affect the state of the membrane is not known at present. The enzymes already tested and hemoglobin can be excluded from consideration. Our results indicate that the factor is a monomeric, anionic protein of low mol wt. Its low stability in vitro may be the result of a tendency to aggregate or adsorb. A very low concentration (<1 µg/mL, as judged by the

staining intensity of the fraction in gel electrophoresis) is required for promotion of invasion. It is thus most likely an enzyme or cofactor. Our earlier evidence^{4,28} suggests that phosphoryl turnover on cytoskeletal proteins, in particular spectrin, may be closely associated with the invasion process, and cytoplasmic as well as membrane-bound kinases or phosphatases are thus likely to be involved.

ACKNOWLEDGMENT

We thank Dr J.P. Brockes for much help with FPLC and Dr N. Spencer for advice on fractionation of the hemolysate.

Immunophenotyping of Acute Myeloid Leukemia Using Monoclonal Antibodies and the Alkaline Phosphatase–Antialkaline Phosphatase Technique

By Curtis A. Hanson, Kazimiera J. Gajl-Peczalska, Janet L. Parkin, and Richard D. Brunning

The leukemic cells from 41 cases of acute myeloid leukemia (AML) and 17 cases of acute lymphocytic leukemia (ALL) were immunophenotyped by the alkaline phosphatase–antialkaline phosphatase (APAAP) immunocytochemical technique utilizing eight monoclonal antibodies (MoAb) reactive with cells of myeloid origin and seven MoAb reactive with lymphoid antigens. Ninety percent of the cases of AML reacted with one or more of the pan-myeloid MoAb, My7, My9, or 20.3. Reactivity of the myeloid panel of MoAb showed some correlation with the French-American-British (FAB) classification of AML. Five of six cases of acute promyelocytic leukemia (APL) were HLA-DR negative; the one HLA-DR–positive APL had a minor population of HLA-DR–negative promyelocytes. OKM5 and/or My4 reacted with 16 of 16 monocytic leukemias. No specific marker of early erythroid development was identified. AP3, a MoAb reactive with platelet glycoprotein (GPIIIa), was specific for acute megakaryoblastic leukemia. Immunocytochemistry was also helpful in classifying seven cases of

AML with equivocal or negative routine cytochemistry. Two cases of AML had minor populations of blasts detected by the APAAP technique that were immunologically distinct from the major blast population; these minor populations emerged as the predominant cell type at relapse. Two cases of ALL expressed multiple myeloid and lymphoid antigens. Two other cases that morphologically were ALL reacted with only myeloid MoAb; one consisted entirely of immature basophils on ultrastructural examination. Immunophenotyping results using the APAAP technique were comparable with those obtained with flow cytometry. The APAAP technique is a reliable method for immunophenotyping leukemia that complements other methods of immunologic evaluation. The primary advantages of this method include its use with routinely prepared blood and bone marrow smears and the ability to correlate immunocytochemical reactions with morphology.

THE DIAGNOSIS and classification of acute leukemia is currently based on a combination of morphological,¹ cytochemical,¹ immunologic,² and cytogenetic³ findings. Although the role of immunologic markers is well established in acute lymphocytic leukemia (ALL),⁴ the recent availability of relatively specific myeloid monoclonal antibodies has given impetus to the application of immunophenotyping in the evaluation of acute myeloid leukemia (AML).⁵⁻¹² Diagnostically, this application relates to two primary points: the distinction of AML from ALL, and the relationship of patterns of monoclonal antibody (MoAb) reactivity to the classification of AML.

Immunophenotyping of leukemia and lymphoma cells has been primarily performed on mononuclear cell suspensions by immunofluorescent methods using either flow cytometry or light microscopy.¹³ Recent studies demonstrated the applicability of immunocytochemistry to the immunologic evaluation of hematopoietic malignancies.¹⁴⁻²² Most of these studies have used the immunoperoxidase technique; however, this enzymatic label has limited application for blood and bone marrow specimens because of difficulties in ablating the endogenous peroxidase activity in myeloid cells.²³ The recently developed immunoalkaline phosphatase methodology obviates this difficulty and greatly enhances the use of immunocytochemistry in the immunologic study of both lymphoid and myeloid leukemia.¹⁴⁻¹⁸

The present study describes the results of the application of the alkaline phosphatase–antialkaline phosphatase (APAAP) immunocytochemical technique to the immunophenotyping of 58 cases of acute leukemia, both myeloid and lymphoid, using routinely prepared, air-dried blood and bone marrow smears.

MATERIALS AND METHODS

The case population for this study consisted of 58 patients with acute leukemia diagnosed in the Hematopathology Laboratory at the University of Minnesota Hospital between January 1985 and

March 1986; 41 of the patients were diagnosed as AML, and 17 were diagnosed as ALL. Studies on 32 AML and 12 ALL cases were performed on specimens taken prior to chemotherapy; 9 AML and 5 ALL cases were studied at relapse.

Morphologic classification was based on criteria established by the French-American-British (FAB) Cooperative Study Group.¹ The 41 cases of AML were subclassified as follows: M1, 5 cases; M2, 10 cases; M3, 4 cases; M3 variant, 2 cases; M4, 12 cases; M5a, 1 case; M5b, 3 cases; M6, 3 cases, and M7, 1 case. Bone marrow specimens were prepared according to previously described methods.²⁴ Cytochemical studies included myeloperoxidase (MPO), sudan black B (SBB), and nonspecific esterase (NSE).²⁶⁻²⁸ Terminal deoxynucleotidyl transferase (TdT) determination was performed on all specimens by indirect immunofluorescence.²⁸ Ultrastructural evaluation included routine transmission electron microscopy and myeloperoxidase and platelet peroxidase ultracytochemistry.^{29,30}

Monoclonal antibodies. Sixteen MoAbs that react with cells of myeloid origin were initially evaluated³¹⁻⁴³; the following eight were selected because of their apparent utility in distinguishing AML from ALL and in establishing an immunophenotypic pattern correlating with the FAB classification of AML: HLA-DR, My7, My9, 20.3, My4, OKM5, OKT9, and AP3. Expression of HLA-DR, which is present on multiple cell types including myeloblasts,³¹ is thought to be absent from granulocytes beginning at the promyelocyte stage of differentiation.³² My7,³³ My9³⁴ and 20.3³⁵ are antibodies reactive with most stages of granulocytic and monocytic differentiation; 20.3

is also expressed on erythroblasts.³⁵ My4³³ and OKM5³⁶ are reactive with cells of monocytic origin; in addition, OKM5 reacts with erythroblasts, platelets, and megakaryocytes.³⁶ OKT9, an antitransferrin receptor antibody,³⁷ reacts with erythroid precursors, thymic lymphocytes, and high mitotic rate tumor proliferations. AP3, a MoAb that recognizes platelet glycoprotein IIIa (GPIIIa),³⁸ can be identified on platelets, megakaryocytes and megakaryoblasts.¹⁸

The other eight myeloid MoAb were not found to add significant differentiation data. Leu M4³⁹ and 20.2³⁵ reacted only with mature granulocytes. Leu M3,³⁹ Leu M1⁴⁰ and OKM1³⁶ identified cells that were morphologically obvious as monocytes, neutrophil myelocytes, or segmented neutrophils. R10,^{41,42} an antiglycophorin A MoAb, was present on late basophilic, polychromatic and orthochromatic erythroblasts but did not react with proerythroblasts and myeloblasts. My10, which is present on hematopoietic stem cells,^{43,44} may be expressed on both lymphoblasts and myeloblasts.

A panel of seven lymphoid monoclonal antibodies, B4,⁴⁵ BA1,⁴⁶ J5,⁴⁷ BA3,⁴⁸ T11,⁴⁹ OKT6⁵⁰ and Leu3,⁵¹ was used to determine B or T cell lineage.

Reagents. Alkaline phosphatase antialkaline phosphatase immunocomplexes were prepared as described by Cordell et al.¹⁴ Calf intestinal alkaline phosphatase (Sigma Chemicals, St Louis) was added at a final concentration of 5 mg/mL to tissue culture supernatant containing mouse monoclonal anti-alkaline phosphatase antibody, which was provided by Dr David Mason, Oxford, England. Unconjugated rabbit antimouse Ig was obtained from Dakopatts (Santa Barbara, CA).

Naphthol-AS-BI, levamisole, fast red TR salt, and trizma base were obtained from Sigma; 0.05 mol/L of Tris-buffered saline (TBS), pH 7.6, was used to dilute all antibodies and the APAAP enzyme complex and was also used as a wash for slides between incubation steps.

Naphthol-AS-BI (2.6 mg) was dissolved in 0.2 mL of dimethyl formamide (Matheson, Coleman, and Bell), followed by the addition of 9.8 mL of 0.1 mol/L of TBS, pH 8.2. Levamisole and fast red TR salt were added at a final concentration of 1 mmol/L and 1 mg/mL, respectively. The substrate solution was then filtered.

Immunocytochemical staining. Immunocytochemical studies were performed on routinely prepared, air-dried blood and bone marrow smears using the APAAP technique after the method of Cordell and colleagues.^{14,18} In brief, slides were fixed in a cold (4°C), 2.5% formalin-acetone mix for 30 to 60 seconds. Primary MoAb was applied for a 30-minute incubation period. Slides were then incubated for 30 minutes with rabbit anti-mouse Ig, the secondary antibody that forms a bridge between the primary MoAb and the APAAP complex, which was then applied for 60 minutes. Following the 60-minute incubation with the APAAP complex, the slides were reincubated with the rabbit anti-mouse antibody for 10 minutes and the APAAP complex for 30 minutes to enhance the intensity of the labeling reaction. This double-bridge procedure for enhancement of the reaction product was described by Vacca.⁵² All incubation procedures were performed in a moist chamber at room temperature and were followed by washing in TBS. The reaction product was developed using the alkaline phosphatase substrate, which was applied for 20 minutes. Slides were then rinsed in tap water, counterstained with Gill's hematoxylin, and coverslipped with glycerin mount. The percentage of positive reacting cells was determined by the assessment of 300 nucleated cells. Positivity with a MoAb was defined as reactivity with >20% of the leukemic cells. There was some variability in the intensity of staining between antibodies and between the different cases. A positive reaction was defined as a cell having an intensity of staining greater than that seen in background residual myeloid cells and in a negative control specimen; equivocal staining was interpreted as a negative reaction. Mouse myeloma ascitic fluid, which contains all immunoglobulin subclasses, was used

as a negative control antibody. The use of fixed cells in the APAAP procedure avoids nonspecific Fc binding problems; incubation of viable cells in solution with antibodies may lead to Fc binding of MoAb in monocytic leukemia with flow cytometric methods.

Thirty-three of the 41 cases of AML and 14 of the 17 cases of ALL were immunophenotyped by flow cytometry using EDTA blood and/or heparinized bone marrow aspirate samples obtained from the same bone marrow procedure as that used for the APAAP study. MoAbs used included HLA-DR and MCS2,⁵³ a myeloid MoAb that recognizes an antigen similar to that identified by My7. The myeloid MoAbs My4, My7, My9, and OKM5 were used in the later stages of the study in 13 cases. Lymphoid MoAbs used in the flow cytometry portion of the study included BA1, BA3, 35.1 (sheep erythrocyte receptor antibody), and OKT6.

RESULTS

Acute myeloid leukemia. Thirty-seven of the 41 cases of AML (90%) reacted with 1 or more of the 3 myelomonocytic antibodies My7, My9, or 20.3 (Table 1); 11 of the cases reacted with all three antibodies. Thirty of the cases (73%) reacted with My7 and 25 (68%) with My9; 88% of the cases reacted with either My7 or My9. Four of the 41 cases did not react with any of these three antibodies; 1 was subclassified as FAB-M1, 2 were classified as M2, and 1 was classified as M7 (megakaryoblastic leukemia).⁵⁴ The case of M7 reacted with AP3, an anti-GPIIIa MoAb. The three cases of non-reacting M1 and M2 were cytochemically positive with MPO and SBB. The one case of M1 had 16% myeloperoxidase-positive blasts; 12% blasts expressed My7, which was lower than our defined threshold of positivity with MoAb. One of the cases of M2 was a therapy-related myeloid leukemia. Myeloid antigen expression was also negative by flow cytometry in the other nonreacting case of M2.

The eight myeloid MoAbs were also evaluated for their ability to discriminate the FAB classification of AML (Table 1). Four immunophenotypic patterns correlated with the FAB subtypes. First, HLA-DR was negative in 5 of 6 cases

Table 1. Cytochemistry and MoAb Reactivity (APAAP) in 41 Cases of Acute Myeloid Leukemia

of acute promyelocytic leukemia (M3), including 2 cases of the hypogranular variant. The one positive HLA-DR case (Fig 1) consisted of a proliferation of typical-appearing promyelocytes with extensive coarse granulation; cells with multiple Auer rods were identified. Although the majority of promyelocytes in this case were HLA-DR positive, 23% of the promyelocytes were HLA-DR negative. HLA-DR reactivity was present in the majority of cases of AML-M1 and M2 (13 of 15) and in all the monocytic leukemias. Less than 20% of the blasts in two cases of M6 and in the one case of M7 were positive with HLA-DR. Second, all monocytic leukemias reacted with My4 and/or OKM5. In addition, five cases of M1 and M2 showed My4 reactivity on 26% to 52% of the leukemic cells. OKM5 positivity was also detected on erythroblasts and megakaryocytes. Third, OKT9 reacted with erythroblasts, including proerythroblasts, and some myeloblasts in the erythroleukemias; myeloblasts in two cases of M1 also reacted with OKT9. Fourth, AP3 was a specific marker for M7. A positive reaction with AP3 was only observed in the platelets, megakaryocytes, micromegakaryocytes, and megakaryoblasts. Blasts in the other sub-

Fig 2. Left: Bone marrow smear from a patient with acute monoblastic leukemia showing several monoblasts. Nonspecific esterase staining was negative. Wright's-Giemsa Original magnification $\times 1,000$; current magnification $\times 500$. Right: Several OKM5-positive monoblasts mixed with negative staining cells. Alkaline phosphatase-antialkaline phosphatase (APAAP), hematoxylin counterstain Original magnification $\times 1,000$; current magnification $\times 500$.

types were uniformly negative with AP3. The one case of M7 was confirmed with platelet peroxidase ultracytochemistry.

Immunophenotyping was also compared with routine cytochemistry. Three cases classified as M1 by morphology were cytochemically equivocal or negative with MPO and SBB and showed positive reactivity with one or more of the myeloid MoAbs My7, My9, or 20.3; one was positive with OKM5 and My4, suggesting a monocytic component. Two cases of M4 and one of M5a (Fig 2) had equivocal or negative staining of the leukemic blasts with NSE. The blasts from all three cases reacted with My4 and OKM5, confirming the monocytic lineage; all cases had monocytic features by electron microscopy.

Two cases of AML-M6 had minor populations of megakaryoblasts and monoblasts, respectively, identified immunocytochemically at diagnosis. In both cases, the minor population emerged as the predominant leukemic cell type at relapse, megakaryoblastic in one (Fig 3) and monoblastic in the other.

None of the 41 cases of AML showed reactivity with the B lineage MoAb. Ten cases (24%) reacted with Leu-3, which is

Fig 3. Left: Bone marrow smear from a patient with acute erythroleukemia showing a single blast (arrow) staining with AP3, a monoclonal antibody (MoAb) to platelet glycoprotein IIIa. Alkaline phosphatase-antialkaline phosphatase (APAAP), hematoxylin counterstain Original magnification $\times 1,000$; current magnification $\times 500$. thought to recognize a cytoplasmic antigen present in monocytes/macrophages.⁵⁵ The intensity of staining was less than that usually found on Leu-3-positive helper T cells. Ten AML cases reacted with Leu-3; seven were FAB-M4 and three were FAB-M5.

Acute lymphocytic leukemia. Fourteen of the 17 cases of ALL reacted with one or more of the B cell lineage MoAb; one case exhibited a T cell phenotype. Four cases of ALL showed unusual immunophenotyping with the MoAb (Table 2). Virtually all blasts in two cases (nos. 1 and 2) reacted with both lymphoid (B lineage) and myeloid MoAb. A high percentage of the leukemic cells in case 1 had MPO-positive granules by ultracytochemistry; chromosome studies showed a normal 46XY karyotype. Electron microscopic evaluation of case 2 showed undifferentiated blasts with negative ultracytochemistry, compatible with an ALL; cytogenetic studies showed a 47XY,+21 karyotype. The intensity of staining with the lymphoid and myeloid MoAb did not differ in these two cases.

Two cases (nos. 3 and 4) classified as ALL by morphology and TdT positivity were negative with all the lymphoid MoAbs; both reacted with multiple myeloid MoAb (Fig 4). Ultrastructurally, case 3 consisted entirely of immature basophils (Fig 5); basophilic granules were not apparent by light microscopy. Cytogenetic studies showed a 46XY karyotype. Case 4 occurred in an 85-year-old man who had a leukocyte count of $446 \times 10^9/L$ and died within 12 hours of admission. No chromosome analysis was performed.

Correlation of immunocytochemistry with flow cytometry. There was good correlation of the immunophenotype results in the 47 cases evaluated with both the APAAP and flow cytometry techniques; there were no discrepancies in the classification of the leukemias between the two methods. Minor variations in the percentage of reacting cells were sometimes noted and were probably related to the different methods of specimen preparation.

DISCUSSION

The utility of MoAbs in the diagnosis and classification of malignancies of the hematopoietic system is well established.^{2,4-8} The initial studies with these markers primarily used flow cytometry or microscopic immunofluorescent techniques. The introduction of immunocytochemistry has considerably expanded the potential application of immunophenotyping acute leukemia. This increased utility relates primarily to the application of immunocytochemical methodology to routinely prepared blood and bone marrow smears and cytospin preparations.¹⁴⁻²¹ Immunocytochemistry allows

Fig 4. Left: Bone marrow smear from a patient with acute lymphocytic leukemia showing lymphoid-appearing blasts. Right: Blasts from same patient showing My7-positive staining. direct visualization of the reactivity pattern of individual leukemic cells with the MoAb.

The diagnostic utility of MoAb in the evaluation of cases of acute leukemia, either by flow cytometry or immunocytochemistry, relates to two primary points: the distinction between AML and ALL and the correlation of patterns of antibody reactivity with the classification of AML. In addition,

Fig 5. Electron micrograph of a peripheral blood leukemic blast from the same case as shown in Fig 4 illustrates peroxidase-positive granulation (arrows). Peroxidase activity is lacking in the nuclear envelope and rough endoplasmic reticulum. Lead citrate only. Original magnification $\times 19,000$; current magnification $\times 12,350$. Inset: At higher magnification, the peroxidase-containing granules show a speckled pattern of positivity typical for basophil granules. Original magnification $\times 39,000$; current magnification $\times 25,350$.

Case	DR	B4/BA1	CALLA	OKT6/T11	My7	My9	20.3
1	+	+	+	-	+	+	+
2	+	+	+	-	+	ND	+
3	+	-	-	-	+	+	+
4	-	-	-	-	-	+	+

My4, OKM5, OKT9, and AP3 were negative in all cases studied. Abbreviation: ND, not done.

tion, MoAbs make possible more ready recognition of proliferations of more than one cell line in leukemias of mixed lineage.

The use of MoAbs in the evaluation of cases of AML is of more recent origin than in ALL. Because of the several possible differentiation patterns in the myeloid system, the results have not been quite as distinct as in the lymphocytic leukemias.⁵⁻¹¹ A study of 196 AML patients from the Cancer and Leukemia Group B (CALGB) showed My9 reactivity in 70% and My7 expression in 57% of cases.⁷ Neame and colleagues found 87% of 75 cases of AML reacted with My9 and 75% with My7; 96% expressed My9 and/or My7.⁵⁶ My7 and My9 also appear to be highly specific for myeloid leukemias. Griffin and co-workers found reactivity in only 1 of 109 cases of ALL with My7 and 2 of 109 with My9.³⁴

The results from the present study demonstrate that, as in flow cytometry techniques, multiple pan-myeloid MoAb must be used in the evaluation of acute leukemias with immunocytochemical methodologies; 88% of the cases of AML in this series was positive with My7 and/or My9. The MoAb 20.3, which recognizes an antigen present on immature myeloid cells, monocytes, and erythroid cells,³⁵ had a pattern of reactivity similar to that of My7 and My9. The blasts from three cases of AML did not react with any of the myeloid or lymphoid MoAb; MPO and SBB were positive in all three cases. These results underscore the importance of cytochemistry in the classification of AML.

None of the lymphoid MoAbs used in this study except Leu-3 reacted with any of the cases of AML. The lymphoid MoAb identified all but two cases of ALL diagnosed by morphology and TdT positivity; the blasts from both cases reacted with myeloid MoAb. One consisted of immature basophils on electron microscopy. The other case occurred in an elderly male with a marked leukocytosis; no ultrastructural or chromosome analysis was available.

The blasts from two cases of leukemia classified as ALL reacted with both myeloid and lymphoid MoAb. This pattern appears to be an infrequent finding, although some authors have reported 20% to 25% of cases of ALL and AML with mixed immunophenotypes.⁵⁷⁻⁵⁹ The significance of these findings is not clear; it has been reported that cases of ALL that react with myeloid MoAb have a poor response to induction chemotherapy.⁶⁰ Both of the two cases in this study entered remission after the first course of induction chemotherapy.

The reactivity of Leu-3, a marker for helper T cells, with cells of monocytic origin has been previously described.⁵⁵ Wood and associates showed that the normal expression of the Leu-3 antigen on monocytes appears to result from endogenous synthesis and is predominantly cytoplasmic in location.⁵⁵ The APAAP technique, as opposed to routine flow cytometric methods, will detect such cytoplasmic expression as shown in this study.

Studies have shown that myeloid MoAb can be used to subclassify cases of AML.⁵⁻¹² Using a large panel of MoAbs, Neame and colleagues found correlation of the immunophenotype and FAB classification in >80% of 75 cases of AML.⁵⁶ Our results demonstrate that some correlation of immunophenotype with the FAB classification. The lack of

reactivity of HLA-DR in the majority of cases of APL confirms previous observations that the promyelocyte is predominantly HLA-DR negative.^{5-8,32} One case of APL in the current study was HLA-DR positive; however, a small population of HLA-DR-negative promyelocytes was morphologically evident with use of the APAAP technique. This is consistent with the 27% of cases of APL with HLA-DR positivity in the CALGB report.⁷ In contrast to the CALGB finding of HLA-DR expression in two of three hypogranular variants of APL,⁷ the two hypogranular variants in the present study were HLA-DR negative. HLA-DR negativity was not exclusive to APL in the present series since 13% of M1 and M2 cases and 24% of cases of ALL were HLA-DR negative.

The antigens identified by My4 and OKM5 are expressed primarily in M4 and M5 AML; 14 of 16 cases of M4 and M5 were positive with My4 in this study. OKM5 is a MoAb reactive with monocyte determinants and is also expressed on platelets and nucleated RBCs.³⁶ OKM5 was present in 14 of 16 (88%) cases of monocytic leukemia in this study; no other subset showed blast reactivity. The reactivity of OKM5 with platelets, megakaryocytes, and normoblasts did not lead to interpretive difficulties because these cells could be morphologically distinguished with the APAAP technique. OKM5 positivity appeared to begin at the basophilic erythroblast stage; the proerythroblasts and myeloblasts in the erythroleukemias were OKM5 negative. Although some micro-megakaryocytes reacted with OKM5, no megakaryoblasts in the one case of M7 reacted.

No specific and sensitive marker of early erythroid development was identified. R10, an antiglycophorin A antibody,⁴² was found only on cells that were morphologically obvious as erythroblasts beginning at the basophilic stage; no proerythroblast or myeloblast reactivity was noted. This is consistent with other studies showing that this MoAb labels only post-CFU-E stages of development.⁴² As a result, R10 would be of limited value in cases of M6 with markedly immature RBC precursors. OKT9, a MoAb to the transferrin receptor,³⁷ was present on some of the myeloblasts in addition to all the erythroblasts in the erythroleukemias. Blast reactivity with OKT9 was also found on myeloblasts in two cases of M1, however, and may be detected in some cases of ALL.

Previous reports showed that MoAbs against GPIIb/IIIa or IIIa have utility in the diagnosis of M7.^{16,18} The ultrastructural detection of platelet peroxidase is probably the earliest marker of megakaryocytic differentiation and remains the diagnostic standard.^{30,61} Immunologic analysis with MoAb allows more rapid identification, however, at less expense.

Although antibody reactivity with anti-factor VIII antibodies may be observed in some cases of megakaryoblastic leukemia,²² reactivity with MoAb to GPIIb/IIIa is a more sensitive marker of megakaryoblasts than is reactivity with anti-factor VIII.⁶¹

Although immunophenotyping may provide helpful confirmatory data in the classification of AML, the majority of cases in this study were readily classified on the basis of routine morphology and cytochemistry. All seven cases of AML with negative or equivocal routine cytochemistry

reacted with one or more of the myeloid MoAbs, however. These findings suggest that immunocytochemistry may be an important tool for identifying blasts of granulocytic or monocytic lineage when routine cytochemistry is negative.

The APAAP technique also facilitates morphological identification of immunologically heterogeneous cell populations. Two cases of untreated AML had low numbers, <5%, of blasts that were immunocytochemically different from the major population. The minor populations eventually emerged as the predominant cell type at relapse. Detection of such minor populations of leukemic cells may not be possible with flow cytometry because most MoAbs are not leukemia-restricted and react with normal myeloid elements.

This study and another report from this laboratory¹⁸ show that results obtained with APAAP immunocytochemistry are comparable to those obtained with flow cytometry; variations in percentages between methods occur in individual cases. Immunocytochemistry offers advantages over flow cytometry in that routinely prepared blood and marrow smears and cytospin preparations may be used; this is useful when retrospective immunophenotyping may be desirable or when specimens and instrumentation for flow cytometry are not available. Interpretation of results is similar to the

interpretation of myeloperoxidase or nonspecific esterase cytochemistry.

Use of APAAP immunocytochemistry requires strict adherence to high technical standards. The quality of reagents and antibodies must be assured, as in any immunophenotyping procedure; positive and negative controls must be evaluated in all specimen batches. The use of a dilute (2%) formalin-acetone mix for a short time (30 seconds) gives excellent cytomorphology of the cells and maintains surface and cytoplasmic antigenicity. Although antigenicity is usually maintained for several months if slides are stored with dessicant at room temperature (personal observation) or frozen at -20°C ,¹⁴ careful evaluation of controls is necessary when using stored material. Nonspecific reactivity must also be assessed; alkaline phosphatase activity in neutrophils can be effectively inhibited by levamisole.¹⁴ Endogenous phosphatase activity in macrophages can be diminished by maintaining an alkaline reaction (pH 8.2).¹⁴

Immunocytochemistry with the APAAP technique is a relatively new but reliable procedure and is an important addition to currently used methods for evaluating acute leukemia.

The Gene Located at Chromosome 18 Band q21 Is Rearranged in Uncultured Diffuse Lymphomas as Well as Follicular Lymphomas

By Ming-Sheng Lee, Mark B. Blick, Sen Pathak, Jose M. Trujillo, James J. Butler, Ruth L. Katz, Peter McLaughlin, Frederick B. Hagemeister, William S. Velasquez, Angela Goodacre, Ann Cork, Jordan U. Gutterman, and Fernando Cabanillas

The karyotypic abnormality $t(14;18)(q32;q21)$ is reported to occur in 75% of follicular lymphomas. This translocation results in the rearrangement of a putative oncogene *bcl-2*, which resides at chromosome 18 band q21 (the 18q21 gene). Using two human genomic DNA fragments cloned from the chromosome 18 band q21 as probes, we analyzed 65 uncultured human lymphoma samples by the Southern blot technique. The 18q21 gene was rearranged in 18 of 26 (69%) follicular lymphomas, 3 of 5 (60%) follicular lymphomas transformed to large cell lymphomas, 8 of 20 (40%) diffuse large cell lymphomas (DLCLs), and 2 of 7 (29%) small noncleaved cell lymphomas (SNCs). Our analysis detected rearrangement of the 18q21 gene in 10 of 13 (77%) cases in which the $t(14;18)(q32;q21)$ translocation

was found by cytogenetic techniques. Our analysis also proved helpful in difficult karyotyping situations: (a) identifying the donor chromosome fragment as chromosome 18 band q21 in 4 of 9 (44%) cases that cytogenetically displayed a 14q+ chromosome of unknown origin, and (b) identifying a rearrangement of chromosome 18 band q21 in 12 of 18 (67%) cases that cytogenetically yielded no cells in metaphase. We also demonstrated three cases of submicroscopic rearrangement of the 18q21 gene. In our studies, patients with DLCLs and rearrangement of the 18q21 gene had a significantly higher incidence of extranodal involvement when compared with patients with DLCLs and no 18q21 gene rearrangement ($P = 0.03$).

RECENT DEVELOPMENTS in cytogenetics and molecular genetics have provided us with a better understanding of the potential genetic mechanisms of tumorigenesis. Several consistent karyotypic abnormalities have been observed in human B cell lymphomas.¹⁻³ Some of these somatic mutations involve reciprocal translocations of a protooncogene and an immunoglobulin gene. About 75% of Burkitt's lymphomas cytogenetically display the $t(8;14)(q24;q32)$ translocation, and the remaining 25% of cases show either the $t(2;8)(p11;q24)$ or the $t(8;22)(q24;q11)$ translocation.⁴ The common feature of these translocations is the involvement of chromosome 8 band q24 where the *c-myc* oncogene resides.⁵ Breakpoints on the counterpart chromosomes occur within the chromosome 14 band q32, chromosome 2 band p11, and chromosome 22 band q11 where the immunoglobulin heavy chain gene, κ light chain gene and λ light chain gene, respectively, reside.^{6,7} The role of the immunoglobulin genes in these instances is still controversial. In vitro studies have shown that the *c-myc* oncogene in these situations is dysregulated and overexpressed.⁸⁻¹⁰ Transgenic mice bearing the *c-myc* oncogene coupled to the immunoglobulin enhancer sequence frequently develop a fatal lymphoma.¹¹

A similar karyotypic abnormality, $t(14;18)(q32;q21)$, has been observed in ~75% of follicular lymphomas, which as a group are one of the most common human B cell malignancies. By analogy, a putative oncogene *bcl-2*, residing at chromosome 18 band q21, has been postulated. Recently, human genomic DNA fragments from this region were cloned from lymphoid cell lines carrying the $t(14;18)(q32;q21)$ translocation by three different groups of investigators.¹²⁻¹⁴ Using these probes, these investigators demonstrated that the gene located at chromosome 18 band q21 (the 18q21 gene) is rearranged in ~60% of follicular lymphomas.¹³⁻¹⁵

This report explores the extent of the rearrangement of this putative oncogene in all forms of human malignant lymphomas simultaneously with cytogenetic analysis, particularly on uncultured cells obtained directly from tumor biopsies or aspirates.

MATERIALS AND METHODS

Procurement of tissues. Fresh uncultured tissues were obtained from diagnostic specimens from 65 patients at The University of Texas MD Anderson Hospital and Tumor Institute at Houston, Houston, Texas (32 lymph node biopsies, 25 lymph node aspirates, 3 bone marrow aspirates, 1 bone biopsy, 1 peripheral blood, 2 pleural fluid aspirates, and 1 ascitic fluid aspirate). All of these samples were reviewed by a member of the hematopathology section and the cytopathology section in the department of pathology and proved to be involved by lymphoma.

Tissue typing. All 65 samples were classified according to the Working Formulation of non-Hodgkin's lymphomas for clinical usage.¹⁶ The determination of follicular or diffuse architecture in the samples of lymph node aspirates was based on the histopathology of the same lymph node whenever possible or on a lymph node biopsy from another site. A subset of patients who displayed follicular large cell lymphoma (FLCL) or diffuse large cell lymphoma (DLCL) histologically, but who initially were diagnosed as having follicular small cleaved cell lymphoma (FSC) or follicular mixed small cleaved and large cell lymphoma (FM), were categorized as transformed follicular lymphoma. The tumor immunophenotype was determined by using one or more markers including IgG, IgM, κ light chain, λ light chain, B1, J5, Leu-1, Leu-2, Leu-3, Leu-4, T11, etc. as described.¹⁷

Preparation of DNA and Southern blot analysis. High-mol-wt DNAs were prepared by a modification of the method described previously.¹⁸ The DNAs were digested with various restriction endonucleases, size-fractionated in 0.8% agarose gels by electrophoresis, and then transferred onto nitrocellulose filters as described by Southern.¹⁹

Probes were nick-translated with [α -³²P] to a specific activity of 1 to 3 $\times$ 10⁸ cpm/ μ g of DNA. Hybridization was carried out at 42°C overnight in the presence of 10% dextran sulfate. The filters were then extensively washed with 0.1% sodium dodecyl sulfate (SDS)/0.1X sodium chloride and sodium citrate (SSC) at 65°C. Autoradiography was done at -70°C with intensifying screens.

Probes used. Two human genomic DNA fragments located at chromosome 18 band q21, subsequently called *bcl-2* and 18q21, were kindly supplied by Drs C.M. Croce and S.J. Korsmeyer, respectively^{12,13} (Fig 1). The probe 18q21 was a 1.5-kilobases (kb) *Hind*III-*Eco*RI insert. The probe *bcl-2* was a 2.8-kb *Eco*RI-*Hind*III insert. An immunoglobulin heavy chain J_H gene probe was provided by Korsmeyer.²⁰ An *N-myc* probe was obtained from American Type Culture Collection (ATCC, Rockville, MD).

Cytogenetic analysis. Cytogenetic analyses were simultaneously performed on tissue samples from 51 patients using techniques previously described.^{21,22} Direct preparations were performed first and, if insufficient metaphases were observed, short-term cultures were then performed.

RESULTS

Of the 65 samples we analyzed with probes, 31 showed rearrangement of one of the alleles for the 18q21 gene (Table 1). The rearrangements were confirmed by identification of the rearrangement with both probes (Fig 1) in 27 of the 31 cases or by analysis with two or more restriction enzymes (Fig 2A and B). The four exceptions were cases 14, 21, 24, and 28. Cases 14, 21, and 28 were small samples; thus, there was inadequate DNA to repeat the Southern blot analysis. In case 24, the rearrangement could only be detected by using probe 18q21 and enzyme *Pst*-I, with which the analysis was repeated and the result reproduced.

The molecular breakpoints of these rearrangements mostly clustered within the 4.3-kb *Hind*III restriction fragment (Table 1 and Fig 1). Of the 31 cases that showed rearrangement, analysis with *Hind*III restriction enzyme was available in 23; 20 of these 23 (87%) showed rearrangement within the 4.3-kb *Hind*III restriction fragment. The rearrangements in the remaining three cases (cases 2, 29, and 36) were shown by analysis with *Bam*H1, indicating that the breakpoints occurred outside of the 4.3-kb *Hind*III restriction fragment but within the 20.5-kb *Bam*H1 restriction fragment (Fig 1).

Figure 3 is a representative example of comigration of the rearranged 18q21 gene and the immunoglobulin J_H gene. In addition to the 4.3-kb *Hind*III germline fragment, each of the samples had one or two additional rearranged fragments when analyzed with the 18q21 probe (Fig 3, lanes A1, B1, C1, D1, E1, and F1). The 18q21 probe was then removed, and the filters were rehybridized with a J_H probe (Fig 3, lanes A2, B2, C2, D2, E2, and F2). A rearranged fragment of similar size was detected with both the 18q21 (*bcl*-2) probes and the J_H probe in 28 of the 31 samples, suggesting that the 18q21 gene and the J_H gene are on the same fragment. The filters were again washed to remove the J_H probe and rehybridized with a *N-myc* probe as an internal control. All the samples displayed only the expected 16-kb germline fragment,²³ indicating that those rearranged fragments detected with the 18q21 (*bcl*-2) probes and the J_H probe were not the result of technique artifacts of the assay. A summary

of our results correlating molecular genetic analysis with histopathology and karyotypes is shown in Table 2.

Eighteen of 26 (69%) follicular lymphomas (23 FSC/FMs and 3 FLCLs), 3 of 5 (60%) transformed follicular lymphomas, 8 of 20 (40%) DLCLs, 2 of 7 (29%) SNCs, 0 of 5 T cell lymphomas, and 0 of 2 diffuse small lymphocytic lymphomas showed rearrangement of the 18q21 gene (Table 2).

The clinical manifestations and the Ann Arbor clinical stage of the 20 patients with DLCL were reviewed. Comparison of the eight patients who showed rearrangement with the 12 patients who showed no rearrangement revealed differences that are summarized in Table 3. The patients with rearrangement of the 18q21 gene showed a significantly higher frequency of extranodal disease ($P = .03$).

Cytogenetic analysis was attempted on samples from 51 patients (Table 2). In 18 cases, no cells in metaphase were obtained. Twelve of these 18 (67%) showed rearrangement of the 18q21 gene and comigration with the J_H gene, suggesting the t(14;18)(q32;q21) translocation. Of the remaining 33 cases, 13 displayed the t(14;18)(q32;q21) translocation; 10 of these 13 (77%) showed rearrangement of the 18q21 gene. The three cases that showed no rearrangement indicate that the breakpoints in chromosome 18 occurred outside the 20.5-kb *Bam*H1 restriction fragment within which our analysis was confined. In 4 of the 9 cases (44%) that karyotypically displayed a 14q+ chromosome of unknown origin, we could demonstrate a comigrating fragment that hybridized to both the 18q21 (*bcl*-2) probe and the J_H probe, suggesting that a t(14;18)(q32;q21) translocation existed. Three of the 11 with cytogenetic abnormalities other than the t(14;18) or a 14q+ chromosome showed rearrangement of the 18q21 gene (cases 40, 54, and 55). In none of these three cases could we demonstrate a comigrating J_H fragment. The karyotypes of these patients have been carefully reviewed, with emphasis on the structure of chromosome 18. No abnormalities in chromosome 18 could be detected in any of these three.

DISCUSSION

The t(14;18)(q32;q21) chromosomal translocation has been observed frequently in follicular lymphomas but less

Fig 2. Southern blot hybridization using probe 18q21. The genomic DNAs were extracted from cases 27, 19, 44, 18, 22, 34, and 5, designated I, II, III, IV, V, VI, and VII, respectively. (A) Using enzyme *Hind*III, the 18q21 probe detected a germline band of 4.3 kb. One or two rearranged bands (arrows) were detected in these samples except for case 44 (lane III). (B) Using enzyme *Pst*-I, rearrangements were also demonstrated in cases 27, 19, 18, 22, 34, and 5 (lanes I, II, IV, V, VI, and VII). The sizes of the rearranged bands were similar but not identical.

Fig 3. Comigration of the 18q21 gene and immunoglobulin heavy chain J_H gene. The blot shown in Fig 2A was washed and rehybridized with a J_H probe which recognized a 11-kb germline fragment. Autoradiography shown by probe 18q21 (1); autoradiography shown by probe J_H (2). Cases 27, 19, 18, 22, 34, and 5 are designated A, B, C, D, E, and F, respectively. Rearranged 18q21 gene fragments are demonstrated to comigrate with the rearranged immunoglobulin J_H gene fragments (=).

frequently in DLCL.¹⁻³ Several previous studies showed that this translocation results in the rearrangement of putative oncogene *bcl-2*, which resides at 18q21.¹³⁻¹⁵

The t(14;18) is a unique chromosome translocation at the molecular level. Molecular cloning and DNA sequencing of the crossover sites in seven representative cases revealed that breakpoints on chromosome 18q21 were located within 450 base pairs (bp) of each other, and breakpoints on chromosome 14q32 were located close to the 5' end of one of the J segments of the immunoglobulin heavy-chain gene.^{12-14,24-26} The hybrid 18q21- J_H gene is in head-to-tail juxtaposition. The 18q21 gene component is 5' to the J_H gene component. The t(14;18) breakpoint hot spot on chromosome 18q21 is ~2.7 kb 3' to the *Hind*III restriction enzyme site (Fig 1).²⁴⁻²⁶ The breakpoints on chromosome 14q32 usually occur within J4-J6 segment, which is ~2 to 3 kb 5' to the *Hind*III restriction enzyme site.^{12-14,24-26} Therefore, the rearranged bands detected by the 18q21 probe are usually very similar in size (5 to 6 kb) using enzyme *Hind*III. In most cases, two rearranged bands are detected by the *bcl-2* probe since the breakpoints usually fall within this probe.

DNA restriction fragment length polymorphisms are com-

mon problems encountered in the interpretation of gene rearrangement. In our series, most cases with rearrangement were confirmed by at least two restriction enzyme analyses. When the amount of DNA in the samples was small, only one enzyme assay could be performed. The possibility of rearrangement due to DNA polymorphisms is remote because a survey of samples obtained from >20 normal subjects and patients with tumors other than lymphomas revealed no restriction enzyme (*Bam*H1, *Hind*III, *Sst*-1, *Pst*-1) polymorphism related to the 18q21 gene.^{12,13} In occasional cases (cases 14, 21, and 45), the rearrangement was detected by probe *bcl-2* but not by probe 18q21 using restriction enzyme *Hind*III. In these instances, the germline bands detected by the 18q21 probe actually were broader than that of the control sample, suggesting the presence of a rearranged DNA fragment whose size was similar to the germline DNA fragment. The most likely reason for detection of the rearrangement by the *bcl-2* probe is that the breakpoints on chromosome 18q21 in these instances occurred within the *bcl-2* probe that detected "two" rearranged bands, one similar in size to the germline band and the other different in size from the germline band.

We analyzed a 20.5-kb *Bam*H1 segment of this gene in various types of uncultured human lymphomas and demon-

Table 3. Clinical Stages of 20 Patients With Diffuse Large Cell Lymphoma: Comparison of 8 Cases With Rearrangement and 12 Cases Without Rearrangement of the 18q21 Gene*

Configuration of 18q21 Gene	Stage I-III		Stage IV	
	Nodal Disease	Extranodal Disease†	Bone Marrow Involved	Bone Marrow† Spared
Rearrangement	0	4	0	4
Germline	6	1	4	1

One case showed divergent histology (DLCL in mesenteric lymph node and FM in spleen). The sample that we analyzed displayed DLCL.

*Extranodal disease (including stage IV cases) v nodal disease ($P = .03$ by chi-square analysis).

†Extranodal sites of involvement: base of tongue, palate, thyroid, soft tissue, pericardium, lung, and liver.

strated that a rearrangement within this gene fragment frequently occurs in various types of human B cell lymphomas: 69% of follicular lymphomas, 40% of DLCLs, and 29% of SNCs.

The rearrangement of the 18q21 gene in DLCLs raises a question of whether these cases might actually be follicular lymphomas that transformed into DLCLs. A thorough review of the clinical histories and histopathologies of each case convinced us that they were bona fide de novo DLCLs, except for one in which multiple biopsies from various sites revealed divergent histologies, ie, FM in one site and DLCL in another site. The remote possibility still exists, however, that these cases involved asymptomatic low-grade follicular lymphoma undiagnosed for months or years before transformation.

Review of the clinical manifestations and Ann Arbor stage of the 20 patients with DLCL revealed that the clinical stage of the eight cases in which there was rearrangement of the 18q21 gene was significantly different from that of the 12 cases in which there was no rearrangement. The high frequency of extranodal involvement in the cases with rearrangement is interesting in view of the high frequency of stage IV presentations in patients with follicular lymphoma who typically show the t(14;18) translocation. The clinical behavior of these eight patients will have to be followed closely to determine whether it will be different from that of the 12 patients in whom there was no rearrangement.

Morphological transformation to a more aggressive histologic subtype is a part of the natural history of many follicular lymphomas. Important questions with regard to clonality should be raised: (a) Does the original clone with a rearranged 18q21 gene persist, or does a newly transformed clone take over? (b) Does the original clone acquire a second somatic mutation in the process of histologic transformation?

In our series, three of five cases of transformed follicular lymphomas showed rearrangement of the 18q21 gene. This partly answers the first question, because rearrangement of the 18q21 gene can be preserved in some cases. A precise determination of clonality, however, will require longitudinal follow-up of the cases that showed rearrangement prior to transformation.

Coexistence of the t(14;18) and the t(8;14) translocation has been observed in cell lines derived from a patient with acute B cell leukemia²⁷ and a patient with SNC.¹⁴ In our series, two SNC lymphomas displayed a rearranged 18q21 gene and one carried the t(8;14)(q24;q32) translocation, whereas the other carried the t(8;22)(q24;q11) translocation. The patient with the t(8;14) translocation also had a rearranged *c-myc* oncogene (data not shown). Pegoraro and colleagues postulated that activation of the rearranged 18q21 gene results in a clonal expansion of low-grade malignant B cells, and acquisition of a secondary mutation [eg, t(8;14) or t(8;22)] results in the activation of another oncogene (eg, *c-myc*), leading to a higher grade malignancy.²⁷ To

determine whether these two somatic mutations are sequential events will also require longitudinal studies.

Correlation with cytogenetic analysis in our 13 patients with the t(14;18)(q32;q21) revealed that we could also identify this abnormality by molecular genetic analysis in 10 (77%). That in three cases we were not able to detect the rearrangement suggests that the breakpoints fell outside the 20.5-kb *Bam*HI restriction fragment.

Even though the methodology used in cytogenetic analysis has improved, significant difficulties remain. The technique is cumbersome and requires viable cells. Tumors with a very low proliferative index, such as follicular lymphomas, frequently yield few or no metaphases. Sometimes the donor chromosome for the 14q+ abnormality is uncertain. Furthermore, submicroscopic internal gene rearrangements, if they exist, are impossible to detect by cytogenetic techniques.

Molecular genetic analysis proved very useful in difficult karyotyping situations. We could identify the donor chromosome band as 18q21 in four of nine cases that cytogenetically displayed a 14q+ chromosome of unknown origin. We could also detect the t(14;18)(q32;q21) translocation in 12 of 18 cases that cytogenetically yielded no metaphases. Molecular-genetic analysis has an advantage in that it can be done in tissues stored for months at -20 to -70°C, whereas viable cells are required for cytogenetic analysis. Furthermore, Southern blot analysis requires a small amount of DNA. We were able to perform the molecular genetic analysis simply from the materials of lymph node aspirates. The relatively high frequency (18 of 51) of insufficient metaphases yielded in our studies was in part due to the fact that many of our samples were obtained from lymph node aspirates.

An intriguing finding was the demonstration of three cases (40, 54, and 55) that showed rearrangement of the 18q21 gene without comigration of the *J_H* gene. Further analysis with a *C_μ*, *S_μ*, and *V_H* probe is required to rule out the possibility that the breakpoint on chromosome 14 occurred outside the *J_H* region. The karyotypes in each of these three cases, however, showed an intact chromosome 18, suggesting a submicroscopic rearrangement of the 18q21 gene. Further elucidation of the possible mechanism will require molecular cloning and DNA sequencing.

In summary, rearrangement of the 18q21 gene occurs in various types of B cell lymphomas, including DLCLs and SNCs. For an understanding of clonal evolution, rearrangement needs to be studied longitudinally in transformed lymphomas. Molecular genetic analysis is useful, especially when karyotyping is difficult, and is potentially useful for identifying subsets of lymphoma with unique biological and clinical behaviors.

ACKNOWLEDGMENT

We wish to thank Drs Croce and Korsmeyer for kindly supplying us the *bcl-2* probe and the 18q21 probe. We also wish to thank Joyce Campbell for assistance in the preparation of this manuscript.

Rearranged Antigen Receptor Genes in Hodgkin's Disease

By James Sundeen, Edward Lipford, Michael Uppenkamp, Eileen Sussman,
Larry Wahl, Mark Raffeld, and Jeffrey Cossman

Despite intensive efforts using a wide variety of approaches, the cellular lineage and clonality of the abnormal cells of Hodgkin's disease have remained an enigma. In the present study, cell separation techniques that enriched for Reed-Sternberg cells and their variants were used to generate sufficient percentages of abnormal cells to allow detection of rearrangements in these cell fractions. DNA from the involved tissues of eight Hodgkin's disease patients was subjected to Southern blot analysis to detect rearrangements of T cell antigen receptor genes and immunoglobulin genes. Immunoglobulin gene rearrangements were found in three of five cases in which Reed-Sternberg cells and their variants were enriched by cell separation techniques to cell frequencies >1%. Rearrange-

ments of immunoglobulin heavy chain genes occurred in two cases, and a λ light chain gene rearrangement occurred in a third case. Rearrangements were not detected in lymphocyte fractions or in unseparated cells prepared from the same tissues. The putative Hodgkin's cell line, L428, also contained rearrangements of immunoglobulin heavy and κ and λ light chain genes and, in addition, harbored a single T cell receptor β gene rearrangement. These findings indicate that Reed-Sternberg cell-enriched fractions contain clonal cell populations and provide a lead, at the molecular genetic level, to a possible lymphoid derivation of the Reed-Sternberg cell.

© 1987 by Grune & Stratton, Inc.

THE APPLICATION of monoclonal antibody phenotyping analysis, cytogenetics, and molecular genetics has identified virtually all non-Hodgkin's lymphomas as clonal neoplasms of lymphocytes.¹⁻⁷ In contrast, little is known regarding the cellular derivation, or even clonality, of the Reed-Sternberg cells of Hodgkin's disease (reviewed in refs. 8 and 9). Immunological and cytochemical analyses of Hodgkin's disease tissues have fostered an array of conflicting findings that have led to many alternative speculations. On the basis of these investigations, Hodgkin's disease has variously been suggested to be a neoplasm of B cells,¹⁰⁻¹⁴ T cells,^{14,15} monocytes/macrophages,^{16,17} interdigitating reticulum cells,^{18,19} or myeloid cells.²⁰ Consequently, no definitive features have emerged to classify precisely the lineage of Reed-Sternberg cells.

Cell biology investigations of Hodgkin's disease have been hampered by several natural factors. One prominent obstacle has been the relative paucity of Reed-Sternberg cells in Hodgkin's disease and a vast predominance of supposedly "normal" cellular elements—lymphocytes, plasma cells, histiocytes, and eosinophils.^{8,21,22} Thus, unlike most non-Hodgkin's lymphomas, the presumed neoplastic cells of Hodgkin's disease are a minor fraction of the total cell number, often <1%, which is generally insufficient for functional studies, cytogenetics, or molecular genetic analysis.^{7,23}

Moreover, it has been remarkably difficult to generate and maintain bona fide, continuous Reed-Sternberg cell lines. Although several cell lines have been cultured, some of these either have not been immortalized²⁴ or were contaminated by

cells derived from other sources.²⁵ One cell line, L428, derived by Diehl and colleagues from the pleural effusion of a patient with previously treated nodular sclerosing Hodgkin's disease has been maintained for >6 years.²⁶ Whether the L428 cell is indeed the direct descendant of a Reed-Sternberg cell, a secondary neoplasm, or a lymphoblastoid cell is not known, since the primary Reed-Sternberg cells from that patient have not been genetically compared with the L428 cell line. The L428 cell remains a possible candidate as a Reed-Sternberg cell, however, since it carries karyotypic abnormalities,²⁶ shares an immunoreactive surface membrane protein with Reed-Sternberg cells (Ki-1 or Hefi-1),^{27,28} and has a phenotype slightly reminiscent of the Reed-Sternberg cell.²⁶

The focus of the present study was to determine the clonality and lineage of Reed-Sternberg cells by molecular genetic analysis of their immunoglobulin and T cell receptor genes. The success of this approach holds promise in that it is sensitive, provides direct evidence of clonality without necessitating cytogenetics, and can be used to identify lineage-related markers without gene expression.^{7,23,29-31} Because cells from Hodgkin's disease might be separable by physical methods,³² our strategy was to apply cell separation procedures to enrich the percentage of Reed-Sternberg cells to threshold levels needed to detect gene rearrangements by Southern blot analysis. By isolating Reed-Sternberg cells, we have begun to explore the molecular biology of Hodgkin's disease.

MATERIALS AND METHODS

Tissues and cells. Involved lymph nodes and spleens were obtained from eight patients with nodular sclerosing Hodgkin's disease (Table 1). Cases were unselected, and no attempt was made to restrict the study to cases with high percentages of Reed-Sternberg cells. Cases of lymphocyte-depleted Hodgkin's disease were excluded from analysis because of the high likelihood that many may actually be non-Hodgkin's lymphomas.^{33,34} Cases of mixed cellularity or lymphocyte-predominant Hodgkin's disease were not available. All patients were advised of procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent.

Fresh tissue samples were finely minced in RPMI 1640 culture medium (GIBCO, Grand Island, NY) and subsequently digested

with collagenase type IV 1.0 mg/mL (Sigma Chemical, St Louis) for 30 to 90 minutes at room temperature with constant stirring. Cell viabilities throughout all procedures were consistently >90%. Cyto-centrifuge slides of the cell suspensions were prepared for morphological and immunostaining analyses.

Cell suspensions were fractionated by Ficoll-Hypaque (Lymphoprep, Accurate Chemical and Scientific, Westbury, NY) or Percoll (Pharmacia, Piscataway, NJ) density-gradient centrifugation or by elutriation. Ficoll-Hypaque separation was performed by layering 8 mL of suspended cells ($\sim 10^7$ /mL) over 4 mL of Ficoll-Hypaque in a 15-mL conical tube for 30 minutes at 400 g at room temperature. Both the interface and pellets were saved for analysis. Percoll solutions were prepared in accordance with the instructions of the manufacturer using 45% to 60% isosmotic Percoll solutions with a density ranging from 1.050 to 1.076 g/mL. An aliquot of 1 mL of cells at 5×10^7 /mL was spun through 9 mL of gradient for 20 minutes at 400 g at room temperature. A control gradient containing standardized beads was simultaneously run to determine density positions. Morphological analysis of Wright's-stained cyto-centrifuge slides was used to evaluate the optimal density range for separation of Reed-Sternberg cells and variants from the remaining cell population. Once this density range was determined, a two-step discontinuous isosmotic Percoll gradient was performed, which trapped the enriched Reed-Sternberg cell fraction between the selected densities (1.051 and 1.069 g/mL). A large volume of cells (20 to 25 mL at 5×10^7 /mL) was separated using the discontinuous Percoll gradient.

The splenic cells obtained from Hodgkin's patients were also separated by counterflow centrifugal elutriation with a Beckman JE-6B elutriation system and rotor as previously described,³⁵ with the exception that the separation media was Dulbecco's phosphate-buffered saline (DPBS) without calcium and magnesium (Biofluids, Rockville, MD). Prior to elutriation, 4 to 8×10^8 spleen cells were incubated at 37°C in 40 mL of DPBS containing 1 mg/mL of deoxyribonuclease (Sigma) for 30 minutes. The cells were then loaded into the elutriation rotor, which was spinning at 1,960 rpm, at a flow rate of 8 mL/min. One hundred fifty milliliters were collected at this flow rate and constituted the first fraction. Subsequently, the cells in fractions 2 through 6, each containing 150 mL, were collected at flow rates of 11, 13.6, 16.4, 18.0, and 19.2 mL/min, respectively. The last fraction, number 7, was comprised of cells that eluted at the final flow rate after the centrifuge was stopped.

Samples from appropriate fractions were viably stored over liquid nitrogen as described. Cyto-centrifuge slides were prepared and used for differential counts (1,000 cells) and immunostaining (see below). DNA was extracted from the majority of cells (1 to 3.5×10^8 cells), as outlined below.

Cell lines used in these studies were L428²⁶ (V. Diehl, University of Cologne) and the African Burkitt lymphoma, Raji (American Type Culture Collection, Rockville, MD). Peripheral blood mononuclear cells were isolated by Ficoll-Hypaque gradient from a normal individual.

Immunophenotyping. Cyto-centrifuge preparations were stained with monoclonal antibodies using an indirect avidin-biotin-peroxidase complex (ABC).³⁶ The percentage of positive cells was determined by scoring 500 to 1,000 cells per slide.

Monoclonal antibodies and their sources included Leu-1, Leu-2, Leu-3, Leu-4, and Leu-M1 (Becton Dickinson Monoclonal Antibodies, Sunnyvale, CA); B-1, B-4, (Coulter Immunology, Hialeah, FL); Hefi-1 (Dr Richard Fisher, Loyola University); and anti-Tac (Dr Thomas Waldmann, National Cancer Institute).

Gene rearrangement analysis. High-mol-wt DNA was extracted from unseparated specimens, Reed-Sternberg cell-enriched fractions, Reed-Sternberg cell-depleted fractions, and the L428 cell line²⁶ by a standard phenol-chloroform ethanol precipitation technique.³⁶ When only small numbers of cells ($<40 \times 10^6$) were

available, DNA was extracted by ultracentrifugation with a guanidine thiocyanate-cesium chloride gradient.³⁶ DNA was subjected to restriction fragment digestion, Southern transfer, and probed with genomic clones of human immunoglobulin J_H, J_K, C_κ, C_λ, T cell γ gene J region (J_γ) and cDNA of the T cell receptor β subunit constant region (C_β), and a full-length cDNA (T_α), as detailed in previous reports.³⁷⁻³⁹ For each sample, BamHI-, EcoRI-, and HindIII-digested DNAs were probed with J_H and C_β, BamHI digests with C_κ, and EcoRI digests with C_λ, J_γ, and T_α probes were hybridized with blots containing L428 DNA digested with BamHI, EcoRI, and HindIII.

For Southern blot sensitivity analysis varying proportions of DNA obtained from Raji cells were mixed with DNA from normal polyclonal splenic lymphocytes. DNA was digested with EcoRI, and conventionally prepared Southern blots were probed with J_H.

RESULTS

Cell separation. Unfractionated cell suspensions of tissues involved by Hodgkin's disease contained <1% Reed-Sternberg cells and variants, except case 4, which was comprised of 4% abnormal cells (Table 1). Percentages displayed in Table 1 represent counts determined by morphological analysis of cyto-centrifuge preparations, which were confirmed in all instances by parallel cyto-centrifuge slides stained with Leu-M1,¹⁹ Tac¹⁹ and Hefi-1.²⁸ In each case, most normal cells were lymphocytes that expressed either T or B cell surface markers. Reed-Sternberg cells and their variants were unreactive with all anti-T cell antibodies, B-1, and B-4. In the elutriation cell separation experiments, Reed-Sternberg cells and their variants increased in fractions 5 through 7; thus, these fractions were combined in case 2 with a yield of 6.6% Hodgkin's cells. Enriched fractions of Reed-Sternberg cells were isolated from discontinuous Percoll gradients in cases 1, 4, 5 and 7 (Figs 1 and 2) using predetermined optimal density ranges (Fig 1); the results of large-scale gradient centrifugation separations are listed in Table 1.

Leu-M1 and Hefi-1 staining confirmed the percentages of Reed-Sternberg cells and variants in the enriched fractions (Fig 3). Lymphocyte fractions contained <0.1% Leu-M1- or Hefi-1-positive cells in all cases. As previously demonstrated by other researchers,^{40,41} Reed-Sternberg cells often formed

Fig 1. Percoll gradient centrifugation. A cell suspension of a lymph node involved by Hodgkin's disease was centrifuged through a continuous Percoll gradient as described in the Materials and Methods Section. Cell samples were taken from several densities, and the optimal density for enrichment of Reed-Sternberg cells and variants (RS) was determined by morphological analysis of cytocentrifuge preparations. In this example (case 5), peak RS separation was obtained between 1.051 and 1.069 g/mL.

Fig 2. Density gradient separation of Reed-Sternberg cells and variants (case 5). A cell suspension of an involved lymph node, which contained 0.04% Reed-Sternberg cells and variants, was fractionated by centrifugation through a discontinuous Percoll gradient. (A) Lymphocytes (>99%) were recovered from the pellet (density >1.069 g/mL) (Original magnification $\times 400$; current magnification $\times 263$; Wright's stain). (B) Reed-Sternberg cells and their mononuclear and multinuclear variants were highly enriched in the interface at density 1.069 g/mL (original magnification $\times 400$; current magnification $\times 270$, Wright's stain).

Fig 3. Immunostaining of cytocentrifuge preparations of Reed-Sternberg cell-enriched fraction (case 5). (A) Spontaneous adherence of T cells to mononuclear variants of Reed-Sternberg cells. Reed-Sternberg cells and variants did not react with the anti-T cell antibody Leu-4 (Leu-4, ABC; original magnification $\times 1,000$ current magnification $\times 6,500$). (B) Leu-M1 staining of a mononuclear variant of a Reed-Sternberg cell reveals elaborate dendritic processes that engulf adherent T cells (Leu-M1, ABC; original magnification $\times 1,000$, current magnification $\times 6,500$).

spontaneous rosettes with autologous T cells (Fig 3A). Dendritic processes elaborated by Reed-Sternberg cells and their variants were stained by Leu-M1 and appeared to engulf adjacent T cells (Fig 3B). The functional meaning of this intercellular activity is not known.

Gene rearrangement. DNA obtained from intact, unseparated, Hodgkin's disease samples was initially screened for gene rearrangements. As in previous studies using this approach,³⁰ no rearrangements were detected (Fig 4). Therefore, subsequent analyses were performed with DNA from fractionated cell populations. Sufficient DNA (usually >100 μ g) was extracted from fractions of interest to allow analysis with each probe and multiple restriction enzymes. In three of

Fig 4. Southern analysis of immunoglobulin κ genes from unfractionated Hodgkin's tissues. Filter hybridization of *Bam*HI digests of genomic DNA obtained from cases 1 through 4 showed no evidence of κ gene rearrangement. Case numbers are shown above each lane. Adjacent dashes indicate the germline *Bam*HI restriction fragment size (12 kilobase, kb) hybridizing with the C_κ probe.

the eight cases (cases 2, 6, and 7), immunoglobulin gene rearrangements were identified in the Reed-Sternberg cell-enriched fractions (Fig 5, Table 1). In contrast, in these same cases, rearrangements were not apparent in either the unseparated cells or in the Reed-Sternberg-depleted (lymphocyte) fractions (Fig 5, Table 1). Thus, detectable gene rearrangements were specifically associated with fractions containing $>1\%$ Reed-Sternberg cells and variants. No T_β gene rearrangements were detected in the cases.

The Reed-Sternberg cell-enriched fraction in case 2 showed one rearranged λ light chain allele, but no rearrangements of immunoglobulin heavy chain, κ light chain, or T_β genes were seen. Although light chain gene rearrangements are found in B cells, it is unusual to find a light chain gene rearrangement without a concomitant heavy chain gene rearrangement.⁴² This finding might be attributable to a technical factor, such as comigration of rearranged and germline bands, but no J_H rearrangements were detected despite digestion with *Bam*HI, *Eco*RI, and *Hind*III. Potentially, deletion of a substantial portion of the J_H region during rearrangement might diminish the sensitivity of detection of J_H hybridization. Simultaneous hybridization with the same labeled probe on the same filter, however, demonstrated rearrangements in cases 6 and 7 (Fig 5, Table 1). Alternatively, the λ gene rearrangement in case 2 may have resulted

Fig 5. Immunoglobulin gene rearrangements in Reed-Sternberg cell-enriched fractions. Cell types were separated as outlined in Table 1, and DNA was extracted and analyzed for gene rearrangement in Southern blots. Case numbers are at top. In case 5, no rearrangements of the immunoglobulin heavy chain gene were detected in either the lymphocyte or Reed-Sternberg cell-enriched (RS) fractions. The RS fraction from case 6 contained two nongermline bands (arrows) hybridizing with J_H in *Hind*III-digested DNA. In contrast, no rearrangements were seen in either the unseparated cells or lymphocyte fractions from case 6. In case 2, the RS fraction exhibited a single rearrangement of the λ gene (arrow), whereas no λ rearrangements were detectable in unseparated cells; germline sizes (-).

from chromosomal breakage or DNA deletion within a hybridizing restriction fragment rather than variable region gene joining. No cytogenetics were available, and sequence analysis would be required to resolve this point.

Cases 6 and 7 both displayed J_H rearrangements and no light chain or T_β gene rearrangements. Again, nondetection of rearrangements might be due to differential sensitivities of each probe. Because heavy chain genes are known to rearrange prior to light chain genes in pre-B cells,⁴² our findings may imply a pre-B cell stage of development. This cannot be concluded with certainty, however, since one cannot reliably exclude the possible existence of a light chain gene rearrangement in such a minor cell population.

L428 cells were found to contain gene rearrangements that included one heavy chain, one κ light chain, one λ light chain, and one T_β chain gene (Fig 6). Restriction fragment analysis of the T_α and J_γ genes showed only germline hybridizing bands.

To estimate the sensitivity of Southern blot analysis for the detection of rearrangements in rare clones, a dilution experiment was performed. The B cell (Burkitt's) lymphoma line, Raji, carries two rearranged J_H genes as seen in *Eco*RI-digested DNA. When known amounts of Raji DNA were

Fig 6. Gene rearrangements in the L428 Hodgkin's cell line. By Southern analysis, single gene rearrangements were detected for the β subunit of the T cell antigen receptor (C_β), immunoglobulin heavy chain (J_H), κ light chain (J_κ), and λ light chain (C_λ) (arrows). Location of germline restriction fragments (-).

mixed with DNA obtained from normal polyclonal lymphocytes and digested with *EcoRI*, nongermline bands contributed by Raji cells could still be detected when Raji DNA was diluted to only 2% of the total DNA (Fig 7). Therefore, clones with a frequency of as little as 2% of the cell population are detectable by Southern analysis, thus confirming the findings in Reed-Sternberg cell-enriched fractions.

DISCUSSION

By enriching for Reed-Sternberg cells and their variants using cell separation techniques, we uncovered immuno-

globulin gene rearrangements in Hodgkin's disease. In each of the three primary cases in which rearrangements were detected, Reed-Sternberg cells and variants were enriched to account for >1% of the cell population, a level that was shown to be near the threshold of sensitivity for Southern analysis. Rearrangements were not observed in any of the samples containing <1% Reed-Sternberg cells and variants. Thus, lack of detection of rearrangements in Hodgkin's disease tissue may be a consequence of subthreshold percentages of Reed-Sternberg cells. It should be emphasized that cases studied here were unselected, yet were unequivocally diagnostic examples of Hodgkin's disease. No attempt was made to examine tissues with high percentages of Reed-Sternberg cells specifically, a procedure that might permit inadvertent inclusion of some non-Hodgkin's large cell lymphomas due to difficulties inherent in differential diagnosis.^{33,34} Furthermore, analyses were performed on lymph nodes and spleens involved by Hodgkin's disease, in which the diagnosis is most accurately made.⁴³ With this approach, we avoided ambiguities regarding circulating neoplastic cells⁴⁴ that might well be secondary non-Hodgkin's lymphoma or leukemia arising in a patient with Hodgkin's disease. Based on the findings reported here, evidence that rearrangements occurred in the Reed-Sternberg cells per se is circumstantial, since cell fractions were not purified to homogeneity. For example, although unlikely, a minor clonal B cell or plasma cell population with a density or volume comparable to Reed-Sternberg cells may have been concomitantly enriched in the Reed-Sternberg-containing fractions. Documentation of the gene rearrangements of Reed-Sternberg cells will necessitate the elimination of extraneous cells by further cell purifications. An additional finding of the present study is that no gene rearrangements were identified in the lymphocyte fractions of lymph nodes containing Hodgkin's disease. Thus, no significant clonal population was contained among these cells. Furthermore, the lymphocyte fraction served as a germline control for each patient to guard against restriction fragment length polymorphism.

Our findings indicate a heterogeneity of rearranged genes among cases of Hodgkin's disease. Rearrangement of immunoglobulin heavy but not light chain genes occurred in two cases (6 and 7), and the converse was seen in case 2. Two

Fig 7. Sensitivity of Southern blot. Raji DNA was diluted in DNA obtained from normal polyclonal splenic lymphocytes. The percentages of total DNA contributed by either Raji or lymphocytes is indicated above each lane. DNA was digested with *EcoRI* and probed with J_H . Germline fragment (-); the two rearranged J_H loci in Raji cells (arrows).

cases (4 and 5) with fractions containing relatively abundant Reed-Sternberg cells had no demonstrable rearrangements for immunoglobulin or T cell receptor β chain genes. The inconsistent rearrangement pattern from case to case may simply be technical; thus, rearrangements in minor cell populations might remain undetected. Alternatively, rearrangements may not have occurred, perhaps as a result of incomplete attempts at B cell differentiation. Cells might be arrested at a pre-B cell stage in which immunoglobulin heavy but not light chains rearrange.⁴² Pre-B cells, however, contain terminal deoxynucleotidyl transferase, and this enzyme is not seen in Hodgkin's disease.⁴⁵ Rearrangements resulting from chromosomal breaks rather than immunoglobulin variable region gene recombination could give rise to the Southern blot pattern we observed. Whether chromosomal damage might account for rearrangements in the present cases is not known since cytogenetics were not performed, but some reported examples of Hodgkin's disease carry abnormalities of the long arm of chromosome 14,⁴⁶ where the immunoglobulin heavy chain gene is located.^{47,48}

By identifying immunoglobulin gene rearrangements, our molecular genetic analysis of the Reed-Sternberg-enriched cell fractions demonstrated minor clonal cell populations in Hodgkin's disease. This finding, coupled with earlier reports of clonal chromosomal abnormalities,⁴⁶ argues that Reed-Sternberg cells are clonally expanded in Hodgkin's disease. Whether the clonal cells detected by either approach are indeed the Reed-Sternberg cells or some other cellular component of Hodgkin's disease associated with Reed-Sternberg cells remains to be determined, however.

Our study of Reed-Sternberg cell-enriched fractions corroborates the demonstration by Weiss and associates⁴⁹ of immunoglobulin gene rearrangements in cases of Hodgkin's disease with abundant Reed-Sternberg cells. In that study, as in the present report, rearranged heavy chain genes were found without accompanying light chain gene rearrangements in some cases, a feature that deserves further investigation. In another study, rearranged T_{β} genes in four cases but no immunoglobulin gene rearrangements were reported from a series of eight cases of Hodgkin's disease.⁵⁰ In that study, however, T_{β} rearrangements were detected with a probe contaminated with variable and joining gene sequences that could produce numerous additional germline bands, which are difficult to interpret without matched germline control tissue from the same patient.⁵¹ Rearrangements of either T_{β} or immunoglobulin genes were also identified by Knowles and colleagues in 3 of 15 cases of Hodgkin's disease, but it was concluded that rearrangements were attributable to clonal lymphoid cells rather than Reed-Sternberg cells.⁵¹ No direct evidence was provided, however, to substantiate such an interpretation. As shown in the present report, lack of rearrangements as observed by others would be expected

in a study of unseparated samples. Furthermore, the actual percentage of Reed-Sternberg cells in a specimen is extremely low and probably less than would appear by estimation from a single histological section. Thus, without direct cell counting of the sample, cases with apparently "numerous" Reed-Sternberg cells might well contain an insufficient percentage of abnormal cells for detection of rearrangements by Southern blot. Finally, when a differential diagnosis of Hodgkin's v non-Hodgkin's lymphoma must be made, it is premature at present to derive a diagnosis of Hodgkin's disease based on the *absence* of rearrangement as suggested by Knowles and colleagues.⁵¹ This precaution should be seriously considered in light of the issues that affect the interpretation of gene rearrangements in a rare cell subpopulation, as well as findings reported here and elsewhere.⁴⁹

Rearrangements of immunoglobulin heavy and κ and λ light chain genes in the L428 cell line suggest a B cell lineage for this cell. The usual hierarchy of light chain gene rearrangement⁴² has been violated, since κ light chain gene analysis demonstrated a single band of germline configuration. Thus, one of the two κ alleles has been neither rearranged nor deleted, as would be expected in a B cell with a rearranged λ gene. An explanation for this unexpected rearrangement of light chain genes might be that, since the C_{λ} locus is polymorphic, the single nongermline C_{λ} hybridizing band obtained with *EcoRI* is a restriction fragment length polymorphism. The size of the *EcoRI* fragment (7.0 kilobase, kb) however, is not the size of any of the known polymorphic *EcoRI* fragments (8, 13, 18, and 23 kb)⁵² and therefore can be considered a consequence of rearrangement of the λ gene locus. In addition, L428 carries one rearranged T_{β} gene, an occasional feature of B cell neoplasms.^{53,54} T_{β} gene rearrangements and germline immunoglobulin genes were found in a T cell line, CO, derived from a patient with Hodgkin's disease, but it is not known whether this cell line represents the tumor.⁵⁵ The unusual molecular genetic characteristics of L428 elude precise classification of cellular lineage, but its rearrangement of immunoglobulin genes is a feature shared with our primary cases of Hodgkin's disease; together, these findings might provide a clue as to the derivation of the abnormal cells of Hodgkin's disease.

ACKNOWLEDGMENT

Immunoglobulin gene probes were provided by Dr P. Leder, the C_{β} probe was prepared by Dr S. Pittaluga from a cDNA (YT35) provided by Dr T. Mak, the T_{α} cDNA (PY14) was a gift of Dr T. Mak, and the genomic J_{γ} probe (pH60) was received from Dr T. Rabbitts. We are grateful to the Clinical Oncology Program, National Cancer Institute, for patient material. The L428 cell line was provided by Dr V. Diehl. We thank Dr R. Fisher for Hefi-1 antibody and Dr T. Waldmann for anti-Tac.

Expression on Blood Cells of Sialophorin, the Surface Glycoprotein That Is Defective in Wiskott-Aldrich Syndrome

By Eileen Remold-O'Donnell, Christopher Zimmerman, Dianne Kenney, and Fred S. Rosen

Sialophorin, previously called gpL115, is the heavily sialylated surface protein that is defective in lymphocytes of Wiskott-Aldrich syndrome patients. Using the monoclonal antibody L10 as a probe, sialophorin expression was detected on isolated T lymphocytes and thymocytes, B cell lines, monocytes, neutrophils, and platelets, but not on erythrocytes, fibroblasts, and glioblastoma cells. This unusual distribution pattern suggests that sialophorin is expressed on all circulating cells except erythrocytes. Trace amounts of the sialophorin molecules on lymphocytes are incompletely sialylated, but significant amounts of the molecules on thymocytes are incompletely sialylated. The molecular form of sialophorin on T lymphocytes, thymocytes, and monocytes is the previously characterized species of apparent mol wt 115,000. A newly described

sialophorin species of apparent mol wt 135,000 was found on neutrophils and platelets. The 115,000 lymphocyte/monocyte form and the 135,000 platelet/neutrophil form were shown to be substantially similar. The two forms have approximately the same content of sialylated O-linked carbohydrate units since both undergo the same atypical shift in electrophoretic mobility on desialylation. Both contain the epitope recognized by the monoclonal antibody L2 and the epitope recognized by L10 antibody. Moreover, evidence from another study indicates that the polypeptide portions are identical, cumulatively suggesting that 115,000 sialophorin and 135,000 sialophorin are identical except for the presence on the latter of additional neutral saccharide residues.

© 1987 by Grune & Stratton, Inc.

SIALOPHORIN, previously called gpL115, is the heavily glycosylated lymphocyte surface protein that is altered in the X-linked disorder Wiskott-Aldrich syndrome (WAS).^{1,2} WAS patients have severe dysfunction of platelets (reduced platelet size, number, and function) and of lymphocytes.^{3,4} The lymphocyte functional defect is reflected in recurrent infections, eczema, decreased antibody production to carbohydrate antigens, and decreased proliferative responses in vitro to mitogens and antigens.

In earlier studies, we compared ¹²⁵I-labeled lymphocytes of WAS patients and normal individuals.^{1,2} Sialophorin (gpL115), a surface glycoprotein of apparent mol wt 115,000, was undetectable, or reduced in quantity, and/or present in an abnormal form in eight WAS patients.² Sialophorin identical to the molecule on normal lymphocytes² was purified from the lymphoblastoid line CEM and shown to consist of a ~520 amino acid polypeptide rich in serine, threonine, and proline, ~two N-linked carbohydrate units, and ~100 O-linked units of the sialylated disaccharide galactose-N-acetylgalactosamine.^{5,6}

As a step toward establishing the physiological role of sialophorin and understanding its dysfunction in the WAS, we examined the expression of the molecule on isolated blood cells. We report that there are two forms of sialophorin on blood cells and characterize the distribution of the two species.

MATERIALS AND METHODS

Blood fractionation. Fresh acid-citrate-dextrose, NIH formula A, (ACD)-anticoagulated blood was centrifuged at 2,500 rpm for 3 minutes in a Sorvall HG rotor. Fractions were collected from the blood bag under pressure as follows: platelet-rich plasma (PRP), buffy cells (60 to 80 mL), and erythrocytes (lower half of packed cells); these were processed at room temperature. Hanks' balanced salt solution (HBSS) and media contained 100 U/mL of penicillin and 100 µg/mL of streptomycin.

Lymphocytes. Buffy coat cells were diluted with equal volume Ca²⁺/Mg²⁺-free HBSS with 20 µg/mL of leupeptin, and 20-mL portions were layered onto 17 mL of Ficoll/Hypaque. After centrifugation, the interface mononuclear cells were washed 1 to 4 times in Ca²⁺/Mg²⁺-free HBSS with 2% fetal calf serum (FCS) to remove contaminating platelets. Washed MNLs at 5 × 10⁶/mL in RPMI 1640 with 2% FCS were cultured for 1 hour at 37°C in culture flasks. The nonadherent cells were collected.

T lymphocytes. Lymphocytes were allowed to react with sheep RBCs (SRBCs).⁷ Rosetted cells were pelleted by Ficoll-Hypaque centrifugation, subjected to hypotonic lysis to remove erythrocytes, and pelleted to yield cells that were 97% CD3-positive as detected by fluorescein-conjugated Leu-4 (Becton Dickinson, Mountain View, CA).

Monocytes. Tissue culture dishes (60 × 15 mm) were pretreated with 2 mL of FCS at 37°C for 15 minutes. After removal of the FCS, 15 × 10⁶ mononuclear cells in 3 mL of RPMI with 10% FCS were cultured for 60 minutes at 37°C. Nonadherent cells were aspirated; the monolayer was washed with RPMI with 2% FCS at 37°C. Adherent cells were harvested with a pipette and a rubber policeman after cooling to 4°C. The collected cells were ≥90% peroxidase-positive mononuclear cells; monocyte recovery was ≥90%. In some experiments, monocytes were cultured for 7 days in RPMI with 10% FCS as adherent cells or as nonadherent cells at 2 × 10⁶/mL in Teflon beakers (Nalge Co, Rochester, NY).

Neutrophils. Pelleted blood cells (after removal of PRP) were combined with equal volume 2% dextran in 0.15 mol/L of NaCl for 30 to 40 minutes at 22 ± 2°C to sediment erythrocytes. The supernatant was aspirated, and the leukocytes were fractionated on Ficoll-Hypaque. The pelleted cells were washed in Ca²⁺/Mg²⁺-free HBSS, and residual erythrocytes were removed by water lysis. The cells were 96% neutrophils (Wright's stain).

Platelets. PRP was made 5 mmol/L in EDTA and was combined with 0.2 vol ACD and centrifuged at 800 g × 15 minutes. The pelleted platelets were resuspended in N-Tris-(hydroxymethyl) methyl-2-aminoethane sulphonic acid (TES)/Tyrodes' buffer (10

mmol/L-TES, 136 mmol/L of NaCl, 2.6 mmol/L of KCl, 0.5 mmol/L of NaH_2PO_4 , 2 mmol/L of MgCl_2 , 5.5 mmol/L of glucose, pH 7.4) containing 5 mmol/L of EDTA and washed twice by centrifugation at 800×12 minutes. Platelet preparations contained <1 WBC per 4,000 platelets (Coulter Model S Plus IV).

Thymocytes. Normal thymocytes, teased from thymic tissue removed as a routine part of open heart surgery, were filtered through sterile cotton gauze and were pelleted. (Thymocytes further purified on a Ficoll-Hypaque gave comparable results.)

Cell lines. The human T lymphoblastoid cell lines CEM^{5,8} and MOLT-4⁹ (ATCC) were grown in Dulbecco's medium with 4.5 mg/mL of glucose and 10% FCS. Cell lines were cultured with 100 U/mL of penicillin and 100 $\mu\text{g}/\text{mL}$ of streptomycin. The T lymphoblastoid cell lines HPB-MLT, HPB-ALL, JURKAT, and HUT-78¹⁰ and the B cell line JY (donated by Dr Steven Mentzer, Dana-Farber Cancer Institute, Boston) were grown in RPMI 1640 with 10% FCS. A172, human glioblastoma cells¹¹ and MRC-5 cells,¹² normal human fibroblasts from fetal lung tissue (ATCC) were grown as adherent cells in culture flasks in Dulbecco's medium with 4.5 mg/mL of glucose and 10% FCS and treated at confluence with 0.5% trypsin-0.02% EDTA (Flow Laboratories, McLean, VA).

Diisopropylfluorophosphate and sialidase treatment and lysis of cells. Nucleated cells washed twice at 4°C were incubated with 4 mmol/L of diisopropylfluorophosphate (DFP) without or with 0.02 IU/mL of *Vibrio cholerae* sialidase as described,² diluted with cold HBSS, and pelleted. Nucleated cells (2.5×10^7 or 5×10^7 thymocytes) were extracted with 1 mL of 0.5% NP-40, 10 mmol/L of Tris-HCl, pH 7.4, 150 mmol/L of NaCl, 1 mmol/L of DFP, 3 mmol/L of iodoacetamide for 3 minutes at $22 \pm 2^\circ\text{C}$ and 8 minutes at 4°C . Insoluble material was removed at 12,000 g for 13 minutes. MRC-5 cells were lysed at passage number ~ 35 . Platelets at $2 \times 10^9/\text{mL}$ in TES/Tyroses' buffer with 5 mmol/L of EDTA were solubilized with 1 vol 2% sodium dodecyl sulfate (SDS), 1% NP-40, 20 mmol/L of Tris-HCl, pH 7.4, 150 mmol/L of NaCl at 100°C for 1 minute. Erythrocytes washed three times in cold phosphate-buffered saline (PBS) were lysed in 5 mmol/L of sodium phosphate buffer, pH 8.0 at 4°C . The "ghosts" were washed free of hemoglobin by pelleting¹³ and solubilized at 2 mg protein/mL in 1% SDS, 0.5% NP-40, 10 mmol/L of Tris-HCl, pH 7.4, 150 mmol/L of NaCl, 1 mmol/L of DFP, and 3 mmol/L of iodoacetamide. Some cell extracts were treated with *Vibrio cholerae* sialidase as described.²

Monoclonal antibodies. L10 is a mouse IgG₁ that binds to a cell surface epitope on native and asialo-sialophorin.^{2,5} L2, an anti-sialophorin antibody from a parallel fusion, is an IgE. In double diffusion, L2 reacts with rabbit anti-mouse IgE antiserum giving a line of identity with pure IgE (reagents supplied by Drs Alfred Nisonoff and Seiji Haba, Brandeis University, Waltham, MA) and shows no reaction with isotype-specific rabbit antisera to mouse IgG₁, IgG_{2a}, IgG_{2b}, IgG₃, IgM, and IgA (Litton Bionetics, Charleston, SC). ³⁵S-labeled L2 antibody, obtained by culturing L2 cells with [³⁵S]methionine, was immunoprecipitated by rabbit anti-mouse IgE antiserum; its apparent mol wt is $\sim 250,000$ (nonreduced) and 92,000 and 26,000 (reduced). L2 antibody was purified by $(\text{NH}_4)_2\text{SO}_4$ precipitation and DEAE cellulose chromatography. ¹²⁵I-labeled L2 bound to 260,000 sites per native CEM cell and L10 to 190,000 sites (three experiments; method and L10 data in ref. 5). L2, unlike L10, does not bind to sialidase-treated cells. L2 immunoprecipitates native but not asialo-sialophorin.

SDS electrophoresis and immunoblotting. Cell extracts were heated with equal volumes of 2% SDS in 60 mmol/L of Tris-glycine buffer, pH 6.8 for 2 minutes at 100°C and electrophoresed on 1.5-mm 7.5% polyacrylamide gels.² Near quantitative transfer of sialophorin to 0.2- μm nitrocellulose sheets¹⁴ (Schleicher and Schuell, Keene, NH) was achieved by constant 2.1 A (250 V/2.5 A power supply; Hoefer Scientific, San Francisco) for 4 hours with 42

mmol/L of Tris/190 mmol/L of glycine, pH 8.3 at 4°C in the Hoefer Transphor Cell.

In immunostaining with Vectastain ABC kits (Vector Laboratories, Burlingame, CA), nitrocellulose membranes were treated with 1% normal horse serum in PBS, with L10 ascites diluted 1:1,000 in PBS with 3 wt/vol% nonfat dry milk solids (Carnation Co, Los Angeles) (PBS-milk) for 1 hour, washed in PBS-milk, treated with biotinylated horse anti-mouse IgG in PBS-milk, washed with PBS, treated with biotinylated horseradish peroxidase H premixed with avidin DH in PBS-milk, washed with PBS and incubated with 0.002% 4-chloro-1-naphthol and 0.003% H_2O_2 in PBS for 10 minutes.

For L2 immunostaining, the membrane was treated with 1% normal goat serum, with L2 ascites diluted 1:500 in PBS-milk, washed, treated with 0.8 $\mu\text{g}/\text{mL}$ of affinity-purified rabbit anti-mouse IgE antibody (provided by Dr David H. Katz, Medical Biology Institute, La Jolla, CA) in PBS-milk, washed, and treated with biotinylated goat anti-rabbit IgG and detection reagents.

RESULTS

L10 staining of T lineage cells. Various isolated cells of T lineage were analyzed for sialophorin expression by immunoblotting with the anti-sialophorin monoclonal antibody L10. Total peripheral blood lymphocytes, isolated T lymphocytes and thymocytes expressed sialophorin (Fig 1). Total lymphocytes and T lymphocytes display similar amounts of L10-positive material of apparent mol wt 115,000 and minor amounts of diffuse material of slightly lesser mobility. Thymocytes display several-fold less L10-positive material on a "per cell" basis. The L10-positive material in thymocytes is a

Fig 1. Immunoblot of human T lineage cells stained with L10 antibody. Native and sialidase-treated cell extracts were electrophoresed on Laemmli polyacrylamide gels, transferred electrophoretically to a nitrocellulose membrane, and treated with L10 antibody and immunoperoxidase detection reagents. The L10-reactive native molecules are shown for: L, 10^6 peripheral blood lymphocytes; T, 10^6 isolated T lymphocytes; and Thy, 4×10^6 thymocytes and twice these cell levels for asialo molecules. Arrow on left indicates native sialophorin of lymphocytes (apparent mol wt 115,000); arrow on right indicates asialo-sialophorin (apparent mol wt 150,000).

double band, consisting of the 115,000 component and a regularly detected component of apparent mol wt ~130,000 (Fig 1, lane 3).

Sialidase treatment of T lineage cells. Sialidase treatment converts all L10-reactive species in T lineage cells to the previously described^{2,5} asialo form of apparent mol wt 150,000 (Fig 1), indicating that the heterogeneity of this molecule in T lineage cells is at the level of sialylation. Thus, the minor diffuse material in T lymphocytes and the ~130,000 mol wt component in thymocytes are incompletely sialylated variants of the 115,000-mol-wt molecule.

JY cells, an Epstein Barr virus (EBV)-transformed B cell line, expresses a 115,000-mol-wt L10-reactive molecule (not shown). Untransformed peripheral blood B lymphocytes were not available in sufficient purity and quantity for immunoblotting.

L10 staining of blood cells. Two important observations were made when extracts of various isolated cells were immunoblotted with L10 antibody. First, L10-positive molecules were found not only on lymphocytes, but also on monocytes, neutrophils, and platelets, but not on erythrocytes, fibroblasts, and glioblastoma cells (Fig 2, left panel). Second, two L10-positive molecules were found on normal blood cells. The 115,000 molecule is expressed by lymphocytes and monocytes, and a molecule of apparent mol wt 135,000 is found on neutrophils and platelets (Fig 2, left panel).

Sialidase treatment of blood cells. Sialidase treatment converted the L10-reactive lymphocyte and monocyte molecules to apparent mol wt 150,000 as anticipated (Fig 2, right panel). Sialidase treatment converted the L10-reactive molecule on neutrophils and platelets to apparent mol wt 170,000 (Fig 2, right panel). Thus, variation in sialylation does not account for the difference between the lymphocyte/monocyte and the neutrophil/platelet forms. We further conclude that the lymphocyte/monocyte form and the neutrophil/platelet form have similar content of sialic acid and sialic acid-bearing units because desialylation causes the same unusual quantitative shift in electrophoretic mobility.

Monocytes. In 10 of 15 experiments, monocytes expressed small amounts of the L10-reactive 135,000 mole-

cule in addition to the major 115,000 molecule (not shown). The additional component is not derived from contaminating platelets or neutrophils, as judged by cell staining and by the absence of reactivity of extracts immunoblotted with neutrophil-specific and platelet-specific antibodies (not shown). Monocytes allowed to mature by culturing for 7 days expressed only the 115,000 molecule (13 experiments; not shown).

L2 staining of blood cells. L2 antibody reacts with an epitope on native but not on asialo-sialophorin (Materials and Methods). On immunoblotting with L2 antibody, T lymphocytes and mature monocytes showed a reactive molecule at 115,000; neutrophils and platelets showed a reactive molecule at 135,000 (not shown). Erythrocytes and fibroblasts were negative. The identical staining patterns obtained on native cells with L2 and L10 indicate that the lymphocyte/monocyte molecule and the neutrophil/platelet molecule contain both epitopes.

L10 staining of lymphoblastoid cell lines. L10-reactive molecules were found in native and sialidase-treated T lymphoblastoid cell lines CEM, JURKAT, HPB-ALL, HPB-MLT, HUT-78, and MOLT-4 (Fig 3). Only CEM express the T lymphocyte molecule (native 115,000, asialo 150,000). HUT-78 and MOLT-4 express an L10-reactive molecule like the neutrophil/platelet molecule (native 135,000, asialo 170,000). CEM cells and MOLT-4 were also examined with L2 antibody, and reactive molecules were detected of mol wt 115,000 and 135,000, respectively (not shown). HPB-ALL and HPB-MLT express L10-positive molecules of 135,000 native, 160,000 asialo. The L10-positive molecule of JURKAT with native mol wt 125,000 and asialo mol wt 140,000 differs most from blood cell sialophorin.

Surface location of sialophorin. Whereas sialidase treatment of cell extracts converts all molecules to the asialo form, sialidase treatment of intact cells affects only surface molecules. By the latter treatment, sialophorin of thymocytes, lymphocytes, monocytes, neutrophils, and the lymphoblastoid cells was completely converted to the asialo form (not shown). Thus, sialophorin is exclusively a surface molecule in these cells.

Fig 2. Immunoblot of isolated blood cells and other cells stained with L10. Shown are native extracts of: L, 10^6 lymphocytes; M, 10^6 monocytes; N, 10^6 neutrophils; P, 5×10^7 platelets; E, 50 μ g of erythrocyte "ghost" protein; F, extract of 10^6 MRC-5 normal fetal lung fibroblasts; and G, 10^6 glioblastoma cells (A172). Asialo molecules are for twice these levels of cell extracts. The positions and mol wt (115,000; 135,000) of native sialophorin molecules (left); asialo-sialophorin molecules (right). No L10-positive molecules were detected in native (shown) or asialo (not shown) extracts of erythrocytes, fibroblasts, or glioblastoma cells. Trace components of mol wt <115,000 in native lymphocytes and monocytes result from proteolysis (established in control experiments).

Fig 3. Immunoblot of human lymphoblastoid cell lines stained with L10 antibody. Shown are native (0.5×10^6 cells) and asialo (10^6 cells) extracts of: A, CEM; B, JURKAT; C, HPB-ALL; D, HPB-MLT; E, HUT-78; and F, MOLT-4 cells. Positions of native L10-reactive molecules of CEM cells (115,000 mol wt) and HUT-78/MOLT-4 cells (135,000 mol wt) (arrows, left). Asialo molecules of CEM cells (150,000 mol wt) and HUT-78/MOLT-4 cells (135,000 mol wt) (arrows, right). Only CEM cells express the lymphocyte form of sialophorin.

DISCUSSION

The expression of sialophorin (gpL115) was studied in blood cells. Sialophorin is the sialic acid-rich surface protein, which is altered in the inherited immunodeficiency WAS. Sialophorin was detected on T lymphocytes, thymocytes, B cell lines, monocytes, neutrophils, and platelets, but not on erythrocytes, fibroblasts, and glioblastoma cells. Thus, sialophorin expression appears to be a property of circulating nonerythroid cells and their precursors. This unusual distribution pattern is consistent with the hypothesized function of sialophorin to maintain cells in the circulation (discussed below).

Although their immunoblotting patterns differ, we concluded that thymocytes and T lymphocytes express the same 115,000-mol-wt sialophorin molecule. Small amounts of L10-positive material of lesser mobility in T lymphocytes and a second component in thymocytes were 115,000-mol-wt sialophorin which is incompletely sialylated.

The finding of heterogeneity of sialylation of human thymocyte sialophorin parallels findings with the analogous molecule in the rat called W3/13 antigen or LS GP (leukocyte sialoglycoprotein). LS GP is also less sialylated on thymocytes than on T lymphocytes.¹⁵ The heterogeneity of sialylation of sialophorin and LS GP in thymocytes may reflect the heterogeneity of the cell population.

Two species of L10-reactive molecules were detected on blood cells; these are the previously described mol wt 115,000 species on lymphocytes, thymocytes, and monocytes and the mol-wt 135,000 species on neutrophils and platelets. The 115,000 and 135,000 mol wt species were shown to be substantially similar molecules as follows. Both contain the epitope recognized by L10 antibody and the epitope recognized by L2. Both have approximately the same content of sialylated *O*-linked carbohydrate units since both undergo the same atypical shift in electrophoretic mobility on desialylation.

In a recent study, the polypeptide cores of 115,000-mol-wt sialophorin and 135,000-mol-wt sialophorin were isolated.⁶ The polypeptide cores (mol wt 58,000) were found to be indistinguishable based on chromatographic procedures

including peptide mapping,⁶ thus indicating that the polypeptide portion of the two sialophorin species are identical. We conclude that the mol wt 115,000 and 135,000 species are probably identical except for the presence in the carbohydrate units of the higher mol wt species of additional neutral saccharide residues.

To emphasize the substantial identity of the mol wt 115,000 lymphocyte/monocyte species and the mol wt 135,000 platelet/neutrophil species, we propose that a common name be used. For this reason, we dropped the name gpL115 and replaced it with the name **sialophorin** (sialic acid-bearing molecule). We suggest that the name sialophorin be used for the closely related glycoproteins with different apparent mol wt that are found on lymphocytes, platelets, monocytes, and neutrophils and on precursor hemopoietic cells and related cell lines. Reactivity with L10 monoclonal antibody could be used as a criterion to define sialophorin.

The relatedness of the name sialophorin to the name glycophorin¹⁶ is appropriate because the molecules are chemically related. Both have high content of serine, threonine, and proline, and multiple *O*-linked sialylated carbohydrate units (15 units on glycophorin¹⁷ and ~100 on sialophorin^{5,6}; compositions compared in ref. 5). Glycophorin and sialophorin are reciprocally distributed on circulating blood cells, ie, glycophorin on erythrocytes and sialophorin on platelets, lymphocytes, monocytes, and neutrophils.

The possible relatedness of sialophorin to human lymphoid glycoproteins examined by other investigators was recently summarized (ref. 2, eight studies). Since then, a study has described gp-110, a peanut lectin binding protein of human thymocytes¹⁸ that may be identical to sialophorin. In another study, GP105, the major *O*-glycosidic membrane glycoprotein on EBV-transformed B lymphoblastoid cell lines, which is aberrantly glycosylated in individuals with the Tn blood group, reacted with L10 antibody¹⁹ and therefore meets the criteria for classification as sialophorin. Similarly, gp105, which was also called leukosialin, has multiple properties in common with sialophorin.^{20,21} It is the major sialoglycoprotein on lymphoid and myeloid cell lines and displays varying apparent mol wt. Leukosialin/gp105 molecules should be

classified as sialophorin because they were demonstrated to react with L10 antibody.²⁰ Sialophorin and leukosialin/gp105 are synthesized by *O*-glycosylation of similar size precursors (mol wt 62,000, and 54,000, respectively).^{6,20} Their carbohydrate contents differ, but this is likely due to the choice of cells used as source of the molecules (see below). Their amino acid compositions differ significantly for unexplainable reasons in serine, threonine, proline, and glycine.^{2,20}

Whereas only two forms of sialophorin were detected on circulating blood cells, transformed cell lines express a wide variety of forms of sialophorin (Fig 3 and ref. 20, 21). For example, all T lymphoblastoid cells with the exception of CEM cells express sialophorin species that are different from the 115,000-mol-wt molecule found on circulating lymphocytes (Fig 3). Compositional and lectin analysis of the 115,000-mol-wt sialophorin indicated that the major carbohydrate structures are sialylated units of the disaccharide Gal β 1-3 GalNAc.^{2,5} Direct analysis indicated that the major carbohydrate structures on leukosialin isolated from the "erythroid" cell line K562 are also sialylated Gal β 1-3-GalNAc units.²¹ It thus appears that K562, a cell line from a patient with chronic myelogenous leukemia,²² expresses the sialophorin species found on lymphocytes/monocytes/CEM cells. On the other hand, the oligosaccharides isolated from leukosialin from HSB cells and HL-60 cells (referred to as "myeloid/T-lymphoid leukosialin") are primarily sialylated units of the tetrasaccharide Gal β 1-4 GlcNAc β 1-6(Gal β 1-3)GalNAc,²¹ a structure compatible with the characteristics of platelet/neutrophil sialophorin. Indeed, direct carbohydrate analysis showed that sialylated tetrasaccharides are also the major units on leukosialin of circulating neutro-

phils.²³ It thus appears that "erythroid leukosialin" is the same as lymphocyte/monocyte sialophorin and "myeloid/T-lymphoid leukosialin" as platelet/neutrophil sialophorin.

We hypothesized that sialophorin functions to maintain lymphocytes in the circulation and regulate their orderly senescence and that the central defect in WAS is acceleration of the normal senescence process.^{2,24} This hypothesis was based on consideration of the functional defects in WAS, namely diminished lymphocyte and platelet function,^{3,4} and on the ultrastructural observation of defective surface architecture in WAS lymphocytes.²⁴ We further hypothesize that intact sialophorin functions as a "masking" protein by shielding underlying antigenic sites on other molecules. The structure of sialophorin is particularly suited for this function since it is an extended rod-like molecule bearing ≥ 100 negatively charged sialylated carbohydrate units.^{2,5,6} The loss of sialophorin or the loss of its rod-like structure occurring on removal of sialic acid residues² might expose underlying antigenic sites to which normal circulating antibodies then bind.²⁵ The identification of sialophorin on platelets, neutrophils, and monocytes as well as lymphocytes introduces the possibility that sialophorin functions to maintain various blood cells in the circulation.

ACKNOWLEDGMENT

We thank S. Kevy, D. Kemp, the staff of Children's Hospital Medical Center Blood Bank, and the blood donors for their vital contributions to this study; S. Mentzner for cytofluorographic analysis of T lymphocytes; and D. Katz, D. Melnick, A. Nisonoff, Seiji Haba, P. Pantazis, and S. Mentzner for contributions of materials.

Arginyl-Glycyl-Aspartic Acid Sequences and Fibrinogen Binding to Platelets

By Edward F. Plow, Michael D. Pierschbacher, Erkki Ruoslahti, Gerard Marguerie, and Mark H. Ginsberg

Human fibrinogen has an Arg-Gly-Asp-Ser (RGDS) sequence at residues 572-575 of its A α -chain. Although RGDS-containing peptides inhibit fibrinogen binding to stimulated platelets, these peptides also inhibit platelet binding of human fibrinogen fragment X and rat fibrinogen, which lack RGDS sequences corresponding to A α 572-575. Thus competition between free RGD-containing peptides and internal RGDS sequence at A α 572-575 is not the basis for their inhibition of fibrinogen binding to platelets. Addition of a Thr to the carboxy-terminus and an Asn to the

amino-terminus of the RGDS sequence, the amino acids corresponding to A α 576 and 571 respectively, reduced the inhibitory potency of RGDS-containing peptides by fourfold to tenfold. Arg-Gly-Asp-Phe (RGDF) corresponds to A α 95-98, and the RGDF peptide was an effective inhibitor of fibrinogen binding, fourfold to fivefold more potent than RGDS. Thus, local primary structure may play an important role in regulating the capacity of RGD sequences in proteins to interact with specific adhesion receptors.

© 1987 by Grune & Stratton, Inc.

RECEPTOR-MEDIATED recognition of arginyl-glycyl-aspartic acid (RGD) sequences in proteins may constitute a basic and evolutionarily conserved mechanism of cell adhesion.¹ This recognition specificity plays a fundamental role in regulating platelet adhesive reactions. Fibrinogen (Fg), fibronectin (Fn), and von Willebrand factor (vWF) contain at least one RGD sequence. Agonists such as thrombin induce receptors for Fg, Fn, and vWF on platelets, and the interactions of these adhesive proteins with their platelet receptors mediate or modulate platelet attachment, spreading, and aggregation reactions.² RGD-containing peptides inhibit the interaction of all three proteins with these receptors on thrombin-stimulated platelets³⁻⁵ with a concomitant inhibition of platelet adhesive functions.³⁻⁶ Platelet membrane glycoprotein GPIIb-IIIa, which serves as a receptor for Fg, Fn, and vWF, specifically binds to RGD affinity resins.^{7,8} Taken together these data strongly implicate the RGD recognition specificity in mediating the interaction of the adhesive proteins with platelets and in regulating platelet function.

Fg contains two RGD sequences at residues 95-97 and 572-574 of the 610 amino acid A α chain.⁹ The RGD sequence at residues 572-574 is followed by a serine residue at position 575, giving the same tetrapeptide sequence as in Fn¹⁰ and vWF.¹¹ As RGDS-containing peptides partially or fully inhibit^{4,5} the binding of all three adhesive proteins to stimulated platelets, attention has been focused upon the RGD sequence in the carboxy-terminal aspect of the A α chain. In fact, the inhibitory activity of RGDS peptide on Fg binding to platelets has been interpreted to implicate this sequence directly in the interaction.⁵ Such an interpretation

is consistent with the capacity of isolated A α chains to aggregate platelets;¹² the marked decrease in the capacity of plasmic degradation products of Fg, which lack the carboxy-terminal region of the A α chain, to support platelet aggregation;¹³ and the photoaffinity crosslinking of derivatized Fg with intact A α chains to GPIIb-IIIa.¹⁴ Nevertheless it has not been shown that the inhibition of Fg binding by RGD-containing peptide arises from a competition of these peptides with the internal sequence at A α 572-575. In this study we have attempted to directly address this issue.

The RGD sequence A α 95-97 is flanked by phenylalanine at position 98, creating an RGDF sequence.⁹ There is some latitude in the permissive residues at the X position of RGD peptides for adhesive function. For example, peptides with Ser or Val residues have similar activities in inhibiting Fg binding to platelets⁴ and fibroblast attachment to Fn.¹⁰ Indeed the amino acid residue at this position has been found to influence the recognition specificity of different RGD receptors markedly (Pierschbacher MD, Ruoslahti E, manuscript in preparation). Thus as a second issue we have evaluated whether RGDF-containing peptides are active in inhibiting Fg binding to platelets.

MATERIALS AND METHODS

Proteins. Human Fg was purified from fresh plasma by differential ethanol fractionation¹⁵ followed by ammonium sulfate precipitation. Fg-X was produced by digesting Fg with plasmin at a 1:600 (wt/wt) ratio for 30 minutes at 37°C.¹⁶ The plasmin was inhibited with diisopropylfluorophosphate, and the Fg-X was purified by high-performance liquid chromatography (HPLC), as described by Stickland et al,¹⁷ but on a TSK-4000 column. Fg-X migrated as a single broad band on sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) under nonreducing conditions with an estimated mol wt of ~250,000. Further characteristics of this fragment are presented in "Results." Fn was isolated from plasma by affinity chromatography on gelatin-Sepharose (Pharmacia Fine Chem, Piscataway, NJ),¹⁸ and vWF was isolated by cryoprecipitation followed by molecular exclusion chromatography.¹⁹ Rat Fg was purified from rat plasma (Pelfreeze Biologicals, Rogers, AR), as described for human Fg. The isolated proteins were radioiodinated by a modified chloramine T procedure, and free ¹²⁵I was removed by dialysis. As previously reported,^{20,22} specific activities range from 0.5 to 2 μ Ci/ μ g, and the precipitability of all radioactive ligands in 15% trichloroacetic acid exceeded 92%.

Peptides. Peptides were synthesized on an Applied Biosystems model 430 peptide synthesizer (Foster City, CA) using PAM resins and t-Boc amino acid purchased from Applied Biosystems. Peptides were cleaved from the PAM resin with HF. The homogeneity of the peptides exceeded 85%, as assessed by reverse-phase chromatogra-

phy on C18 columns on the HPLC. Peptide concentrations were determined by amino acid analyses of 24-hour hydrolysates in 6N HCl.

Platelet-binding assays. Platelets were isolated from fresh human blood drawn into acid-citrate-dextrose by differential centrifugation followed by gel filtration in modified Tyrode's buffer, pH 7.3, containing 2% bovine serum albumin.²⁰ The binding of the various ligands to the platelets were analyzed as previously described.²⁰⁻²² Briefly, platelets at a final concentration of 1×10^8 /mL were incubated with the radiolabeled adhesive proteins, at their estimated K_d , and varying concentrations of the selected inhibitory reagent. The binding reaction was initiated by addition of the platelet agonist, 10 μ mol/L ADP or 0.5 units thrombin/mL, and the interaction was quantitated after a 30-minute incubation at 22°C for Fg and vWF and 37°C for Fn by separating bound from free ligand by centrifugation of 50 μ L aliquots of the reaction mixture through 20% sucrose. The ID_{50} of a peptide, the concentration of a peptide that produced 50% inhibition of the binding of the radiolabeled ligand observed in the absence of peptide, was determined from dose titration curves. As nonspecific binding, measured by addition of a 50-fold excess of nonlabeled protein, never exceeded 12% of total binding of the ^{125} I-ligands, corrections for nonspecific binding were not employed in these calculations. The ID_{50} of the tetrapeptide RGDS on Fg binding was determined on nine separate occasions with two synthetic products during the course of these studies, and the variation in its ID_{50} value was less than twofold.

SDS-PAGE. Vertical slab gels, 10 cm in length, or cylindrical gels, 0.15×7 cm, were run in the buffer system of Weber and Osborn.²³ Sample preparation and subsequent autoradiography and mol estimations were performed as previously described.²⁴

RESULTS

Effect of RGDS peptides on Fg-X binding to platelets. Fg-X is derived by cleavage of Fg at one or more plasmin-sensitive bonds in the A α 195-239 region as well as at B β 42-43.^{25,26} Thus this fragment contains the amino-terminal aspects of the A α chain but lacks the RGDS sequence at A α 572-575. Fg-X binds to platelets albeit with a lower affinity than Fg.²⁷ The capacity of the RGDS peptide to inhibit the binding of Fg and Fg-X to ADP-stimulated platelets was compared. As shown in Fig 1, RGDS inhibited the binding of Fg and Fg-X to ADP-stimulated platelets. This inhibition was dose-dependent and exceeded 85% for both ligands at peptide concentrations ≥ 200 μ mol/L. The inhibitory potency of the tetrapeptide was similar although not identical for Fg-X and Fg; the ID_{50} values on Fg-X and Fg binding were 40 and 16 μ mol/L respectively. This 2.5-fold difference is reduced to 2.0-fold if the residual interaction of Fg-X at high RGDS concentration is considered to represent nonspecific binding.

To exclude that the observed binding of Fg-X (and inhibitory activity of the peptides on this interaction) was due to selective binding of a minor, residual component of intact Fg in the Fg-X preparation, the cell-bound ^{125} I-radioactivity was analyzed by SDS-PAGE. As shown in Fig 2, the added and bound ^{125} I-Fg-X were identical to one another. The estimated mol wt of the major constituent chains of Fg-X at 48, 41, and 24 kDa are clearly distinguishable from those of the constituent chains of intact Fg at 65, 56, and 48 kDa and are consistent with the known subunit composition of Fg-X.²⁸

Fig 1. Effect of Arg-Gly-Asp-Ser on binding of fibrinogen fragment X and fibrinogen to ADP-stimulated platelets. ^{125} I-Fg (0.3 μ mol/L) and ^{125} I-Fg-X (1 μ mol/L) were added with varying concentrations of RGDS to washed platelets at 1×10^8 mL in Tyrode's albumin buffer containing 1 mmol/L CaCl_2 . The platelets were stimulated with 10 μ mol/L ADP, and binding was measured after a 30-minute incubation at 22°C. In the absence of the peptide, $14,000 \pm 600$ Fg molecules and $6,000 \pm 200$ Fg-X molecules were bound per platelet.

Effect of RGDS peptides on rat Fg binding to platelets. As an independent approach to examine the competition between the free RGDS-containing peptide and the RGDS sequence in the carboxy-terminus region of the A α chain of Fg, the capacity of RGD-containing peptides to inhibit the binding of rat Fg to human platelets was examined. As determined from cDNA cloning, the protein sequence of the A α chain of rat and human Fg is predicted to be 64% homologous, but the A α chain of rat Fg is shorter:

Fig 2. Characterization of the radioiodinated fragment X added and bound to ADP-stimulated platelets. The ^{125} I-Fg-X preparation was bound to ADP-stimulated platelets for 30 minutes at 22°C. The cell pellets were extracted with 5% SDS, reduced with 2% 2-mercaptoethanol and electrophoresed on a 4% to 10% polyacrylamide gradient gel in SDS under reducing conditions. An autoradiogram of the dried gel is shown. Lane 1 is the added ^{125} I-Fg-X; lane 2 is the ^{125} I-Fg-X extracted from platelets; and lane 3 shows the constituent A α , B β , and γ chains of intact fibrinogen.

531 v 625 amino acid residues.²⁹ This size difference is apparent from the comparison of the two Fg preparations by SDS-PAGE under reducing conditions (Fig 3), and the gels also attest to the purity of the Fg preparations used in this study. According to the alignment of Crabtree et al,²⁹ rat Fg has a deletion corresponding to A α 566-579 and therefore does not contain the carboxy-terminal RGDS sequence. When rat ¹²⁵I-Fg was bound to human platelets stimulated with ADP, RGDS-containing peptides were capable of inhibiting this interaction. As shown in Fig 4, the two RGDS-containing peptides, GRGDSP and RGDS, inhibited the binding of rat Fg to platelets in a dose-dependent fashion. The ID₅₀ values of RGDS on rat and human Fg were 13 and 18 μ mol/L respectively; the ID₅₀ of GRGDSP was 17 and 29 μ mol/L respectively.

Effect of amino acids adjacent to RGDS on adhesive protein binding to platelets. In considering mechanisms that might regulate the interaction of an RGD sequence, such as in the carboxy-terminus of the A α chain, with an RGD receptor, the influence of the amino acids adjacent to the RGDS sequence on peptide inhibitory function was investigated. The sequence of A α 569-577 of human Fg is Ser-Tyr-Asn-Arg-Gly-Asp-Ser-Thr.⁹ As shown in Table 1, attachment of the Thr to the carboxy-terminus of the RGDS sequence resulted in a sixfold higher ID₅₀. The addition of the Asn residue to the amino terminus caused a further diminution in inhibitory potency. Further extension of the peptide in the amino terminal direction by addition of Tyr and Ser-Tyr was without additional effect. Thus the amino acids immediately adjacent to the RGD sequence, particularly at the carboxy-terminus, can have a significant effect in regulating the inhibitory activity of RGD-containing peptides.

RGD sequences are also found within Fn and vWF, and RGD-containing peptides inhibit the binding of these other

Fig 3. Characterization of isolated rat and human fibrinogen by polyacrylamide gel electrophoresis. Lanes 1 and 2 are human (H) and rat (R) fibrinogen respectively, run on cylindrical 5% polyacrylamide gels under nonreducing conditions. Lanes 3 and 4 are human and rat fibrinogen respectively, run on 7.5% polyacrylamide gels under reducing conditions.

Fig 4. The effect of two RGD-containing peptides on the binding of human (hu) and rat fibrinogen to human platelets stimulated with ADP. Human or rat ¹²⁵I-Fg at 0.3 μ mol/L and varying concentrations of RGDS and GRGDSP were added to platelets at 1×10^8 /mL in Tyrode's albumin buffer containing 1 mmol/L CaCl₂. Platelets were stimulated with 10 μ mol/L ADP, and binding was measured after a 30-minute incubation at 22°C. In the absence of peptides, $18,000 \pm 2,000$ molecules of human fibrinogen and $8,000 \pm 800$ molecules of rat Fg bound per platelet.

two adhesive proteins to platelets.³⁻⁵ In view of the marked effects of the amino- and carboxy-terminal residues adjacent to the RGDS sequences on Fg binding, the influence of the adjacent residues in the sequences of Fn and vWF was evaluated. As the analysis of Fn binding requires the use of thrombin-stimulated platelets, the effect of the peptides tested above on Fg binding to adenosine diphosphate (ADP)-stimulated platelets were also tested on its binding to thrombin-stimulated platelets. As indicated by a comparison of Tables 1 and 2, the potency of the individual peptides Arg-Gly-Asp-Ser (RGDS), Arg-Gly-Asp-Ser-Thr (RDGST), and Asn-Arg-Gly-Asp-Ser-Thr (NRGDST) as inhibitors of Fg binding to either ADP or thrombin-stimulated platelets was similar. For example, the ID₅₀ values for RGDS on Fg binding to ADP- and thrombin-stimulated platelets were 22 and 24 μ mol/L respectively. The sequence of the cell attachment site in Fn is Gly-Arg-Gly-Asp-Ser-Pro.¹⁰ Addition of a Pro to the carboxy-terminus or a Pro at the carboxy-terminus and a Gly at the amino-terminus did not affect the ID₅₀ values of these peptides on Fn binding. These results are consistent with

Table 1. Effect of RGDS and the Amino Acids Adjacent to A α 572-575 on Fibrinogen Binding to ADP-Stimulated Platelets

¹²⁵I-Fg (0.3 μmol/L); ¹²⁵I-Fn (0.3 μmol/L) or ¹²⁵I-vWF (400 ng/mL) were incubated with 1×10^8 platelets/mL, varying concentrations of the indicated peptides, and 0.1 units/mL thrombin for 30 minutes in Tyrode's albumin buffer containing 1 mmol/L CaCl₂. In the absence of peptides, the molecules/platelets of Fg, Fn, and vWF were $17,500 \pm 3000$, $29,600 \pm 4000$ molecules/platelet; and 700 ± 50 ng/10⁹ platelets, respectively.

previous data reported from our laboratories.³ Similar results were found with vWF, where the sequence of the RGD region is Pro-Arg-Gly-Asp-Ser-Gln. Attachment of a Gln to the carboxy-terminus and a Pro to the amino-terminus only had a slight effect on the potency of the peptides as inhibitors of vWF binding to platelets. Thus in contrast to Fg, extension of the RGDS sequence in the amino- and carboxy-terminal direction had minimal effect on the capacity of the RGDS-containing peptides to inhibit Fn and vWF binding to platelets. Also included in Table 2 is the effect of RGDST on Fn binding to platelets. Although this peptide was considerably less potent than RGDS in inhibiting Fg binding, it had a potency similar to RGDS on Fn binding. This suggests that the variable inhibitory activity of the peptides is, at least in part, established by the particular adhesive protein interacting with the cells.

Effect of RGDF peptides on Fg binding to platelets. The second RGD sequence in the Aα chain is contained within the peptide Leu-Arg-Gly-Asp-Phe-Ser (LRGDFS), which corresponds to Aα 94-99. We have also used synthetic peptides to evaluate the effect of a Phe residue adjacent to the Asp residues and of the additional carboxy- and amino-terminal amino acids on the activity of this RGD region. As shown in Table 3, RGDF is an inhibitor of Fg binding to ADP-stimulated platelets and is in fact approximately fourfold to fivefold more potent than RGDS. Attachment of a Ser residue to the carboxy-terminus to generate RGDFS caused a ninefold decrease in inhibitory activity based on the ID₅₀ values. Extension of the peptide in the amino-terminal direction with the naturally occurring residue Leu or with a Gly had little additional effect on inhibitory activity. In comparing the inhibitory activities of the hexapeptides corresponding to Aα 94-99 and Aα 571-576, the former peptide is fourfold more potent. The increased potency of the RGDF relative to RGDS was also observed with Fg binding to thrombin-stimulated platelets and with Fn and vWF as ligands. The ID₅₀ values of RGDF on Fn and vWF binding were 2 and 3 μmol/L, respectively.

Experimental details are the same as in Table 1. In the absence of peptides, $18,200 \pm 600$ Fg molecules were bound per platelet.

DISCUSSION

Synthetic peptides with structures corresponding to small segments of larger proteins have been highly useful in dissecting the recognition specificities of a variety of cell-surface receptors^{10,30,31} including the receptors for platelet adhesive proteins.^{3-6,32} As originally established for Fn³ and more recently demonstrated for Fg and vWF,^{4,6} RGDS-containing peptides inhibit the binding of these adhesive proteins to their inducible platelet receptors. As each of these adhesive proteins contains an RGDS sequence, direct competition between the free RGDS peptides and the RGDS sequences in the proteins is a likely mechanism for the observed inhibition. The data shown in the present study indicate the situation may be more complex in the case of Fg. Namely, the interaction of two Fg forms, human Fg fragment X and rat Fg, which both lack an RGDS sequence corresponding to Aα 572-576 of human Fg, was inhibited by RGDS-containing peptides. Moreover the potency of the RGDS-containing peptides in inhibiting the binding of these Fg forms lacking the RGDS sequence was similar to that observed with intact human Fg containing the RGDS sequence. These observations are consistent with the results of Peerschke and Galanakis,³³ who found that intact fibrinogen and derivatives lacking the carboxyterminus of the Aα chain exhibited similar binding affinities for platelets. It should be emphasized that these results do not exclude that the RGDS sequence at Aα 572-576 of human Fg interacts directly with the platelet. However, competition between the sequence in the protein and the free peptide cannot be the sole basis for the inhibitory activity of the free peptides.

As alternatives to the direct competition between free and protein-contained RGDS sequences, four possibilities may be considered. First, the free peptide may bind to Fg (or the adhesive proteins) and prevent its binding to platelets. This possibility seems unlikely, as the platelet receptor for the adhesive proteins, GPIIb-IIIa, binds directly to RGDS coupled to a solid support,⁷ whereas Fg and Fn do not. Second, RGDS-containing peptides may bind to the platelet and may alter the capacity of the receptor to interact with the adhesive proteins. Such an allosteric mechanism of inhibition cannot be excluded. However, RGD peptides inhibit Fg binding to platelets on which the receptor has been fixed in an induced state with paraformaldehyde,⁴ and the peptides appear to affect receptor affinity rather than the number of binding sites for the adhesive proteins.³ Third, the basis for the inhibitory capacity of the RGDS peptides may rest in their competition with the RGDF sequence at Aα 95-97. This may explain why certain Fg derivatives that contain an

RGDF sequence such as the N-DSK and certain fragment E preparations can inhibit (albeit weakly) the binding of Fg to platelets.^{34,35} Fourth, the RGDS peptides may compete with the carboxy-terminus of the γ chain of Fg for the platelet recognition site(s). Peptides corresponding in structure to the carboxy-terminus of the γ chain of Fg (having the structure LGGAKQAGDV) also inhibit Fg as well as Fn and vWF binding to platelets.^{21,32} We have recently found that both γ chain and RGD-containing peptides coupled to Sepharose bind GPIIb-IIIa and can elute the glycoprotein bound to an affinity column of the other peptide.³⁶ Thus by competing for the same site(s) the RGD peptides could inhibit Fg binding to GPIIb-IIIa mediated by the γ chain sequence, and the RGD sequences in Fg need not interact directly with platelets.

To consider potential mechanisms that might regulate the function of the RGDS sequence in Fg, we examined the effect of the amino acids adjacent to the RGDS sequence on the inhibitory potency of peptides as antagonists of Fg binding to platelets. Indeed the adjacent amino acids significantly influenced the potency of the peptides. RGDST was a considerably less potent inhibitor of Fg binding than RGDS, and NRGDST was still less potent. Thus the local sequence surrounding the RGD residues may play an important role in regulating the interaction of RGD sequences with RGD receptors. This effect of local sequence may preclude an interaction of Fg with platelets via A α 572-576 and may also be the basis for the apparent lack of interaction of Fg with certain cells expressing RGD receptors.^{10,37} In contrast to such very local effects, the overall conformation of Fg might determine the availability of the A α 572-576 sequence. However, the carboxy-terminal of the A α chain is predicted to be highly hydrophilic and flexible.³⁸ We have also subjected A α 551-611 to the secondary structure predictive analyses (Chou-Fasman Program) available at the University of Wisconsin Genetics Computer Group Program.³⁹ The RGDS sequence at A α 572-576 is predicted to be hydrophilic and involved in β turns, according to the predictive analyses of Hopp and Woods⁴⁰ and Chou and Fasman⁴¹ respectively. Similar predictions are also derived for the RGDS sequence within Fn. Thus these predictive analyses provide no basis to

postulate a unique conformation to the carboxy-terminal aspects of the A α chain of Fg which would interfere with the accessibility of this RGDS sequence. Therefore very local effects such as those established by the amino acids immediately adjacent to the RGDS sequence could play an important regulatory role. The amino acids adjacent to the RGDS sequences in Fn and vWF had a minimal effect on the inhibitory potency of RGD-containing peptides on the binding of these other two adhesive proteins to platelets. These data are compatible with a direct role of these RGDS sequences in mediating Fn and vWF binding to platelets. It is also noteworthy that, as emphasized by comparison of the inhibitory potency of RGDST on Fg and Fn binding to thrombin-stimulated platelets (ID₅₀ differences of approximately fivefold), that the same peptide can have differential effects on the binding of the various adhesive proteins to platelets. This provides evidence that the platelet receptors for these adhesive proteins may not be precisely identical. The differences in the ID₅₀ values of the RGD-containing peptides on Fg v Fg-X in Fig 1 and rat and human Fg in Fig 4 is most readily explained in terms of the possibility of more than one recognition site within these ligands, which results in nonidentical binding of the adhesive protein to the platelet.

Finally, it was noted that RGDF was a particularly potent inhibitor of Fg as well as Fn and vWF binding to platelets. This raises the possibility that peptide or nonpeptide analogues based on the RGD sequence can be constructed that could be very potent inhibitors of platelet function. Initial evidence for this has been provided by the publication of Ruggeri et al.⁴² The potential of such analogues as anti-thrombotic agents would depend upon their selectivity for platelets.

Second Marrow Transplants in Patients With Aplastic Anemia Rejecting the First Graft: Use of a Conditioning Regimen Including Cyclophosphamide and Antithymocyte Globulin

By R. Storb, P.L. Weiden, K.M. Sullivan, F.R. Appelbaum, P. Beatty, C.D. Buckner, R.A. Clift, K.C. Doney, J. Hansen, P.J. Martin, J.E. Sanders, P. Stewart, R.P. Witherspoon, and E.D. Thomas

Sixteen (11%) of 146 consecutive patients with severe aplastic anemia prepared for engraftment with cyclophosphamide (200 mg/kg) rejected marrow grafts from their HLA-identical siblings. They were given a second marrow transplant from either the same ($n = 13$) or a second ($n = 3$) HLA-identical sibling between 23 and 743 (median 86) days after the first transplant. The preparation for the second transplant included cyclophosphamide, 50 mg/kg, on each of four successive days. Twelve hours after each of the first three doses of cyclophosphamide, antithymocyte globulin, 30 mg/kg/dose, was infused. One of the 16 patients died from infection too early after the second transplant to be evaluated, two had failure of engraftment and died with infection, one rejected the second graft and is surviving almost 5 years later with full autologous marrow recovery, and 12 had successful and sustained second grafts. Of these 12, six are surviving between 11

months and 7 $\frac{3}{4}$ years. Four of the six have no graft-v-host disease (GVHD), while two have chronic GVHD requiring treatment. Five have Karnofsky scores of 100% and one of 90%. Six of the 12 patients with sustained grafts died between 63 days and 38 months after transplantation, four with infections (related in two patients to chronic GVHD), one with acute GVHD, and one with hemorrhage. The average interval from first to second transplant was 308 days during the past five years, compared to 61 days in earlier patients. Five of seven recent patients are surviving, compared to two of nine earlier patients. In conclusion, successful second transplants after cyclophosphamide and antithymocyte globulin are possible in most patients with aplastic anemia who have rejected their first marrow grafts; however, mortality remains high, with only 40% of the patients becoming long-term survivors.

© 1987 by Grune & Stratton, Inc.

GRAFT REJECTION is associated with a high mortality in patients with severe aplastic anemia given marrow grafts from HLA-identical family members.¹⁻⁶ We reported earlier that only two of 29 patients undergoing graft rejection became long-term survivors.⁷⁻⁹ One of the surviving patients showed full restoration of autologous marrow function, and one had a successful second transplant. Isolated additional cases of successful second transplants have been described.¹⁰⁻¹³ Various conditioning regimens for second transplants have been used, including cyclophosphamide (CY) and total body irradiation (TBI), or procarbazine and antithymocyte globulin (ATG) combined with CY or TBI.⁷⁻¹⁵ All of these regimens had associated toxicities, and in many cases the second graft was not established. Based on a murine study showing synergism between CY and ATG,¹⁶ we first explored alternating CY and ATG to condition a patient who had rejected two preceding marrow transplants.⁷ The success seen in this patient led us to adopt CY/ATG as our conditioning regimen for patients who have rejected their first

graft. We now report its use in 16 consecutive patients with aplastic anemia.

MATERIALS AND METHODS

From October 25, 1977 to August 23, 1985, 146 patients with severe aplastic anemia were transplanted with marrow from their HLA-identical family members following conditioning with CY. Details of the first transplants in these patients have been reported previously.¹⁷⁻¹⁹ Sixteen of the 146 patients (11%) either failed to show evidence of initial marrow engraftment or rejected the first graft. Characteristics of these 16 patients are shown in Table 1. Marrow donors and recipients were HLA-A and HLA-B identical siblings whose cells were mutually nonreactive in mixed leukocyte culture.

Patients were referred after detailed consultation with their physicians and treated after outpatient and inpatient conferences that fully outlined the advantages and disadvantages of the transplantation procedure. Protocols and consent forms were approved by the Institutional Review Board of the Fred Hutchinson Cancer Research Center.

Before first transplantation all 16 current patients received CY, 50 mg/kg intravenously (IV) on each of four successive days. Thirty-six hours after the last dose of CY, donor marrow was infused IV. The day of first marrow infusion was designated day 0. Five of the 12 multiple-transfused patients were also given viable donor buffy-coat cells as reported previously.¹⁸ The four untransfused patients and seven of the 12 multiple-transfused patients did not receive buffy-coat cell infusions. These infusions are not routinely given in untransfused patients¹⁷ nor in transfused patients under the age of 18 years²⁰; six of the transfused patients were in this young age group, while one was transplanted before buffy-coat cell transfusions became part of the transplantation protocol.

Postgrafting immunosuppression consisted of methotrexate in nine, cyclosporine in one, and a combination of methotrexate and cyclosporine in six cases, as previously described.¹⁹

The conditioning for second transplant consisted of CY, 50 mg/kg IV on each of four successive days. At 12-hour intervals following the first, second, and third dose of CY, patients also were given ATG (ATGAM, Upjohn Company, Kalamazoo, MI), 30 mg/kg IV infused over a period of 10 to 12 hours. Marrow for second

transplant was infused 36 hours after the last dose of CY. In 13 cases marrow infusion for the second transplant was supplemented by donor buffy-coat cell infusions. In three cases marrow donors were too young to serve as buffy-coat cell donors.

Assessment of hematopoietic engraftment and grading and treatment of acute and chronic GVHD were done as previously described.²¹⁻²³ Primary therapy of established grades 2 to 4 acute GVHD consisted of methylprednisolone, 2 mg/kg/day, either IV or orally in divided doses for a period of seven to 14 days when the patient's status was re-evaluated. Chronic GVHD was treated with methylprednisolone, either alone or combined with azathioprine (Aza). Marrow aspirates and/or cytogenetic studies usually were performed on days 14, 21, 28, 56, 84, and 365 postgrafting to assess the quality of engraftment.

Results of the study were analyzed as of August 1986.

RESULTS

Tables 2 and 3 summarize the transplantation data and results.

First transplant. Two of the 16 patients failed initial marrow engraftment, while 14 showed rises in granulocyte counts and evidence of marrow cellularity on day 14. Granulocyte counts rose to above 1,000 at a median of 20 days, not different than previously reported for patients with sustained marrow engraftment. In eight of the 16 patients the marrow donor was of opposite sex. Cytogenetic studies in these eight showed predominance of donor type cells in the marrow on day 14 and subsequent occasions, while phytohemagglutinin (PHA)-stimulated peripheral blood mononuclear cells showed a mixture of host and donor karyotypes. An example of cytogenetic findings for one of the patients is shown in

Table 2. Transplantation Data

*In three instances a different HLA-identical sibling was used as marrow donor for the second graft.

Table 4. Rejection was characterized by progressively falling peripheral blood counts, decreasing marrow cellularity, and the appearance of increasing numbers of lymphocytes of host origin demonstrated by cytogenetic analysis after PHA stimulation. The decision to proceed with a second transplant was prompted by the development of severe marrow aplasia.

Second transplant. Second grafts were carried out between 23 and 743 (median 86) days after the first grafts. In all but three cases the same HLA-identical sibling was used as the marrow donor for the second transplant. The median numbers of marrow cells infused in the first and second grafts were comparable. The postgrafting immunosuppression in the second was the same as that used in the first transplant. Acute toxicity associated with ATG administration included skin rash (four patients), fever (eight patients), and hypotension (two patients). One patient developed signs of serum sickness consisting of rash, fever, and arthralgias beginning eight days after ATG infusion.

Following the second graft, one patient died too early to be evaluated (day 4 after second graft), two patients failed to engraft and died with infection (days 18 and 39), and one patient showed initial engraftment followed by graft rejection. The latter patient showed complete recovery of his own marrow and is alive more than 57 months after the first marrow graft with normal hemopoietic function. Twelve patients showed sustained engraftment. Of these 12, six developed acute GVHD grades 2 to 4, two of whom died from mixed bacterial/viral and fungal pneumonia (days 91 and 193) and four of whom developed chronic GVHD. Two of the four with chronic GVHD died with bacterial infections (days 987 and 1085), and two are surviving at 85 and 93 months, one with a Karnofsky score of 100% and one of 90%, both requiring immunosuppressive therapy. Five patients did

not develop acute GVHD, and one had grade 1 acute GVHD. One of these six died with bladder hemorrhage related to thrombocytopenia on day 63, one with pseudomonas aeruginosa pneumonia on day 393, and four are living between 11 and 50 months after the first transplant. Cytogenetic and other blood genetic marker studies in surviving patients showed donor type hematopoiesis in six cases and complete host-type hemopoiesis in one.

The three young patients not given supplemental buffy-coat cell infusions all engrafted and are surviving without evidence of acute or chronic GVHD. All three patients given a second marrow graft from a different donor engrafted, and one is surviving at 7½ years with chronic GVHD.

Over the past five years rejections occurred generally at a later time than was seen before the middle of 1981; this was true both for methotrexate- and cyclosporine-treated patients. Accordingly the interval between first and second transplant increased on the average from 61 to 308 days. Five of seven patients in the latter group are surviving, compared to two of nine in the former group.

Figure 1 illustrates the cumulative probability of survival for these 16 patients as measured from the day of first transplant.

DISCUSSION

By the mid 1970s, graft rejection was recognized as a frequent complication after marrow transplantation for severe aplastic anemia, occurring in 35% to 70% of patients given HLA-identical marrow grafts following conditioning with CY.^{1-3,6,24} Rejection is likely to be caused by sensitization of recipient cells to minor histocompatibility antigens expressed on donor cells through preceding blood transfusions. During the past decade the incidence of rejection has declined to 17% in the series reported by the European and International Bone Marrow Transplant Registries^{4,5} and to 11% in patients transplanted in Seattle.^{18,25,26} The reduction in the frequency of rejection has been attributed both to more aggressive treatment regimens, including TBI, total lymphoid or thoracoabdominal irradiation, cyclosporine,^{4,5,27-32} and the addition of buffy coat cells to the marrow inoculum,¹⁸ and to changes in the quantity and quality of preceding blood transfusion products.^{17,26}

Except in those few patients who have subsequent recovery of autologous marrow function,³³⁻³⁸ graft rejection has remained a serious complication owing to the return of marrow aplasia. For second transplants to be successful, graft rejection needs to be diagnosed promptly and distinguished from other causes of marrow malfunction. Reversible marrow hypoplasia in the setting of a marrow graft can be caused by certain viral infections and also by drugs such as trimethoprim sulfamethoxazole, acyclovir, interferon, or methotrexate.³⁹ Blood genetic markers are most helpful in distinguishing between rejection and marrow suppression. Mixed chimerism (mixtures of cells with host and donor karyotype) has been seen in a majority of patients (58%) early after marrow grafting, while a minority of patients (42%) never showed host cells after transplantation.⁴⁰ Rejection was seen almost exclusively in patients with mixed

Fig 1. Probability of survival (measured from first marrow graft) in 16 patients with severe aplastic anemia given second marrow transplants from HLA-identical siblings (Kaplan-Meier product limit estimates).⁴⁶ Tic marks above the line represent surviving patients with sustained engraftment; the tic mark below the line represents the patient with autologous marrow recovery. Survival is as of August 1986.

chimerism (30% incidence) and was rare in complete chimeras (5% incidence). Persistence of mixed chimerism and/or gradual disappearance of donor type cells, in particular among PHA-stimulated peripheral blood lymphocytes, may be the first signs of graft rejection. Molecular biology techniques, such as restriction-enzyme fragment-length polymorphism studies, will be useful in those patients whose donors are sex matched and who lack distinctive banding markers.⁴¹

Once a diagnosis of graft rejection has been established in the presence of marrow aplasia, conditioning for second transplantation should proceed. We have previously reported second marrow transplants using a variety of regimens in 21 patients carried out 26 to 157 days after the first transplant.^{7,9} Six of these 21 attempts were not evaluable because of early deaths, eight were unsuccessful, and seven were successful with only one of the 21 patients now surviving for more than 11½ years. Eight additional patients with rejection were not given a second transplant; seven of these died with infection and marrow hypoplasia, and one is alive with complete autologous marrow recovery 12 years later.³³ Thus of 29 patients undergoing rejection, only two are surviving.

Isolated successful transplants have been described by other transplant centers.¹⁰⁻¹³ Previous conditioning regimens included combinations of CY and TBI, procarbazine/ATG combined with TBI or CY, and, in one instance, the present combination of ATG and CY. The current experience using this combination proved to be more successful than our past experience with other conditioning regimens, and 12 of 15 evaluable patients showed sustained engraftment. Presumably, the addition of ATG to CY usually provides sufficient immunosuppression to overcome sensitization to minor histocompatibility antigens expressed on donor cells that lead to rejection of the first graft, although a contribution of added buffy-coat cell infusions cannot be excluded. The regimen was generally well tolerated, apart from fevers and chills associated with the ATG infusion. While successful in securing sustained engraftment, the regimen did not prove to be uniformly life saving. Half of the patients with engraftment developed significant acute and/or chronic GVHD and died from associated infectious complications. However, six patients are living with sustained grafts, five with Karnofsky scores of 100% and one of 90%, although two of the six have

chronic GVHD requiring treatment. Graft rejection is presumed to be due to histocompatibility differences involving "minor" antigens. These same differences may account for GVHD when a persisting marrow graft is established, as was observed in half of the cases described here, which may contribute to the mortality.

Over the past five years rejections occurred generally at a later time (on the average ten months after grafting) than were seen before the middle of 1981 (on the average two months after grafting). Results with second transplants in the recent patients were better than those in the earlier group. The reasons for the recent increase in the time to rejection are unclear. Hows et al⁴² described late graft failure in 13% of their cyclosporine-treated patients following discontinuation of immunosuppressive therapy and suggested that cyclosporine had delayed what otherwise might have been early rejection.²⁹ This explanation may be true for some of our patients; however, others have received methotrexate during the first three months after marrow transplantation. An alternative explanation for the late graft failure seen in some of the present patients is the re-emergence of a population of abnormal, immunologically reactive cells (presumably T cells) that were responsible for creating the original aplastic anemia. Evidence that such cells may exist in patients with aplastic anemia is based on previous *in vitro* observations, the response of some patients to treatment with ATG, and the occasional failure of syngeneic marrow grafts to take in the absence of conditioning with CY.^{43,44} In the present patients the increased immunosuppression provided by the combination of ATG and CY may have abolished the abnormal T cell population, thereby setting the stage for sustained allogeneic marrow engraftment. In the absence of *in vitro* assays distinguishing between immunity to an allograft caused by sensitization through blood products and "autoimmunity," it remains unclear which of these mechanisms was operative in the late rejection seen in the present patients.

One of the three patients with failure of sustained engraftment showed complete recovery of autologous marrow function, a finding described previously in isolated patients.³³⁻³⁸ Whether the ATG contained in the second conditioning regimen contributed to this recovery remains conjectural.

In conclusion, while graft rejection has become a lesser problem than it was a decade ago, it remains a significant complication after marrow transplantation for patients with severe aplastic anemia. Early recognition of graft rejection through careful hematologic follow-up and the use of blood genetic markers may permit successful second transplantation after conditioning with ATG and CY, resulting in sustained and stable hematopoietic engraftment.

ACKNOWLEDGMENT

We are indebted to the inpatient and outpatient physicians, nurses, ward clerks, secretaries, technologists, and data processors of the Fred Hutchinson Cancer Research Center and Swedish Hospital Medical Center for their cooperation in this study. We would like to thank the Upjohn Company, Kalamazoo, MI, for supplying antithymocyte globulin. We are grateful to the referring physicians for care of patients after leaving Seattle.

Loss of Myeloid Differentiation Antigens Precedes Blastic Transformation in Chronic Myelogenous Leukemia

By Mary B. Todd, James A. Waldron, Timothy A. Jennings, Lisa S. Rome, Sanford D. Markowitz, Theodore R. Holford, Joseph P. Gardner, John P. Wolak, and Harry L. Malech

In order to determine whether antigenic patterns alter with disease progression and are thereby suggestive of impending blast crisis in chronic myelogenous leukemia, 50 bone marrow biopsy specimens from 32 patients were examined retrospectively using indirect immunoperoxidase labeling with three monoclonal antibodies that detect myeloid antigens. Monoclonal antibodies PMN13F6, PMN7C3, and PMN8C7 detect human neutrophil antigens that first appear at the myeloblast, promyelocyte, and metamyelocyte stages of differentiation, respectively, and persist throughout later differentiation. Percentages of antigen-positive bone marrow cells during the chronic phase were compared with percentages of antigen-positive cells at blast transformation, and time from bone marrow biopsy until blast crisis was correlated with the percentage of bone marrow cells expressing these antigens. Bone marrow biopsy samples from patients in the chronic phase who continue to remain clinically stable 4 to 106 months after biopsy expressed PMN13F6 antigen on $82\% \pm 9\%$ (mean $\pm$ SD) of cells, PMN7C3 antigen on $62\% \pm 14\%$ of cells, and PMN8C7 on $68\% \pm 14\%$ of cells. Bone marrow biopsy specimens obtained from patients 1 or more years prior to blast transformation expressed PMN13F6 antigen on $81\% \pm 12\%$, PMN7C3 antigen on $71\% \pm 16\%$, and PMN8C7 on $64\% \pm 16\%$ of cells. Bone marrow biopsy samples obtained between 2 months and 1 year prior to blast crisis expressed PMN13F6 antigen on $68\% \pm 15\%$, PMN7C3 on $51\% \pm 17\%$, and PMN8C7 antigen

on $46\% \pm 18\%$ of cells. Bone marrow biopsy specimens taken at the time of blast transformation expressed PMN13F6 antigen on $20\% \pm 25\%$, PMN7C3 antigen on $19\% \pm 25\%$, and PMN8C7 antigen on $13\% \pm 25\%$ of cells. The difference between the mean of antigen-positive cells from bone marrow biopsy samples obtained at the time of blast crisis was significant compared with the mean of positive cells from biopsy specimens obtained at all other phases of the disease ($P < .001$ for all three antibodies). There was a positive correlation between loss of myeloid antigens and disease progression as determined by simple regression of log time and correlation analysis (PMN13F6, $r = .6533$, $P < .005$; PMN7C3, $r = .6304$, $P < .005$; PMN8C7, $r = .5215$, $P < .05$). There was a negative correlation between percentage of immature cells and time to blastic crisis ($r = -.6206$, $P < .005$). There was no correlation between the percentage of immature cells present prior to blastic transformation and expression of the antigen appearing at the metamyelocyte stage detected by PMN8C7 ($r = -.3145$, $P < .20$). There was an inverse relationship between the percentage of immature cells and presence of the early appearing antigens detected by PMN7C3 ($r = -.5144$, $P < .05$) and by PMN13F6 ($r = -.7961$, $P < .001$). The emergence of increasing numbers of cells that do not express certain myeloid differentiation antigens in addition to morphological changes may serve as an indicator of impending blast transformation.

CHRONIC MYELOGENOUS LEUKEMIA (CML) is a myeloproliferative disorder with two distinct phases. The first (chronic) phase usually is controllable until progression to the second phase (accelerated or blastic), which is a more aggressive form that is universally fatal in a short time despite treatment with chemotherapy. The median duration of the chronic phase ranges between 2 and 4 years but is extremely variable, with some patients presenting in

the blast transformation stage and others remaining in the chronic phase for many years.¹⁻³

Successful transplantation of bone marrow to individuals with CML has resulted in long-term survival of individuals with this previously fatal disorder.⁴ However, transplantation after blast transformation or during the accelerated phase has been disappointing due to failure to eradicate the leukemia, incomplete engraftment, or additional complications of bone marrow transplantation.⁴⁻⁶ Best results are obtained when patients receive transplants during the chronic phase. However, because transplantation itself has at least a 30% risk of death,⁴ it is appealing to delay bone marrow transplantation until as late as possible in the course of the disease.

Studies by several groups have helped to define prognostic signs that identify patients at the time of diagnosis of CML who are at high risk for early progression to the second phase.⁷⁻¹¹ Other studies have helped to define signs that may indicate transition from the chronic phase to the blastic phase.¹²⁻¹⁵ Prognostic indicators noted at diagnosis that suggest poor prognosis are well documented (ie, lack of a Philadelphia chromosome)^{9,16,17} but fail to provide an indicator of impending transition for an individual patient. Signs such as fever, splenomegaly, increasing anemia, thrombocytopenia, and basophilia are either not specific for an impending aggressive phase or are noted too late in the course of the disease to be of benefit. The appearance of increasing numbers of myeloblasts and promyelocytes in blood or bone

marrow is commonly used as a sign of disease progression, but this criterion alone is often not specific for the time course until that individual patient enters blastic crisis.

In this study we correlated changes in the expression of neutrophil differentiation antigens in bone marrow cells with transition to a more aggressive phase of CML. Fifty bone marrow biopsy specimens from 32 patients were examined retrospectively by using indirect immunoperoxidase labeling with three monoclonal antibodies that detect myeloid differentiation antigens. Our findings indicate that there is a significant difference in the percentage of cells that expressed these antigens at the time of blastic crisis compared with other phases of the disease, that antigen loss preceded blastic crisis, and that there was a correlation between the percentage of antigen-positive cells and time until transformation. Antigenic changes, in combination with other indicators and signs of disease progression, may be useful for the prediction of impending blastic crisis.

MATERIALS AND METHODS

Patients. After appropriate human protection committee validation, paraffin-embedded bone marrow biopsy specimens from patients with the diagnosis of CML were obtained from the Yale-New Haven Hospital Pathology Department. Normal bone marrow samples were obtained when biopsies were done for purposes other than this study, and the results were interpreted as normal by conventional light microscopy. All patients had been advised of the procedure of bone marrow biopsy and the alternative risks of that procedure, in accordance with institutional guidelines, and gave informed consent. Patients were chosen on the basis of availability of adequate bone marrow biopsy material and confirmation of the diagnosis of CML. The charts of all patients were reviewed. The diagnostic criteria for CML were based on conventional criteria including history and physical, a typical peripheral blood and bone marrow picture with increased myeloid elements, and when available, chromosomal analysis and leukocyte alkaline phosphatase score. Differential counts of peripheral blood smears were previously performed by technicians of the clinical hematology laboratory of this hospital. Histochemical studies of bone marrow biopsy and aspirate samples were reviewed. All bone marrow biopsy sections were stained with hematoxylin and eosin for purposes of this study and were examined by two pathologists. Bone marrow samples were evaluated for features such as myeloid-erythroid ratio and percentage of myeloblasts, promyelocytes, and myelocytes.

Monoclonal antibodies. Hybridomas that secrete antihuman neutrophil antibodies were obtained by using a variation of the method of Kohler and Milstein¹⁸ as previously noted.^{19,20} In brief, BALB/c mice (The Jackson Laboratory, Bar Harbor, ME) were immunized with purified normal human neutrophils,²¹ and spleen cells from these mice were fused with SP2/0 Ag14.²² Hybridomas producing antibodies that bind to human neutrophils were cloned by limiting dilution.

Experiments were conducted with monoclonal antibody obtained from filtered spent media from growing hybridoma cultures or from filtered ascites of BALB/c mice injected with hybridomas. Determination of immunoglobulin subclass was done by Ouchterlony analysis²³ using subclass-specific rabbit antimouse immunoglobulin.

Binding of monoclonal antibodies to blood cells. Human neutrophils were separated from heparinized venous blood from normal donors by using Ficoll-Hypaque (Histopaque 1083, Sigma Chemical Co, St Louis) density gradient centrifugation followed by dextran sedimentation and hypotonic lysis of erythrocytes.²¹ Mononuclear cells were separated by using Ficoll-Hypaque density gradient

centrifugation. For some studies mononuclear cells were further separated on a reorienting Percoll gradient to obtain a fraction containing more than 95% monocytes and no neutrophils.²⁴ Cell purity was assessed by Wright-Geimsa stain.

The binding of monoclonal antibodies to blood cells was measured by using an indirect enzyme-linked immunoassay (Bethesda Research Laboratories, Gaithersburg, MD) as previously described.^{19,20} The binding of monoclonal antibodies was also assessed by direct or indirect immunofluorescence as previously described.²⁵ Cells were directly observed (Zeiss microscope) or analyzed by using a Becton Dickinson (Mountain View, CA) FACS IV to quantify binding.

Biochemical characterization of antigens detected by monoclonal antibodies. Neutrophils isolated from the peripheral blood of normal donors were incubated with 2 mmol/L diisopropyl fluorophosphate (DFP; Aldrich Chemical Co, Milwaukee) for one hour at 4°C to decrease proteolysis.²⁶ Neutrophils were then treated with extraction buffer (18 mmol/L Tris-glycine, pH 8.5, 0.5% Triton X-100, 5 mmol/L EDTA, 20 mg/mL chymostatin [Sigma], 5 mmol/L DFP, 5 mmol/L 2-mercaptoethanol) for ten minutes on ice. After centrifugation, the supernatant extract was used for electrophoretic analysis. For sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), extracts were mixed with an equal volume of SDS solubilizing buffer (6% SDS, 6 mol/L urea, 125 mmol/L Tris-HCl, pH 6.9, 4 mmol/L EDTA, 5% 2-mercaptoethanol) and electrophoresed following the method of Laemmli²⁷ with some changes in conditions as previously described.²⁰ Molecular weight determinations (M_r) were extrapolated from curves by using protein standards of known molecular weight. Isoelectric focusing (IEF) or nonequilibrium pH gel electrophoresis (NEPHGE) of cell extracts was done as previously described.^{20,28,29} Cell extract was mixed with an equal volume of IEF solubilizing buffer (8 mol/L urea, 2.5% ampholines of pH 3 to 10 [Bio-Rad Laboratories, Richmond, CA], 1.5% Triton X-100, 0.5 mol/L B-mercaptoethanol) and isoelectric focused into polyacrylamide tube gels containing urea, Triton X-100, and ampholines. After IEF or NEPHGE the gels were extruded into SDS solubilizing buffer and incubated for 30 minutes. The gels were then placed onto polyacrylamide slab gels for SDS-PAGE in the second dimension.

Antigens separated by SDS-PAGE or two-dimensional PAGE were electrophoresed onto nitrocellulose paper and detected by immunoblot (Western blot) analysis by sequential use of the murine monoclonal antibodies, rabbit antimouse Ig, and ¹²⁵I staphylococcal protein A as previously described.^{30,31} Nonspecific antibodies of the same subclass or culture supernatants from a non-immunoglobulin-secreting mouse myeloma cell line were used as controls.

Detection of antigen expression in bone marrow biopsy tissue. Tissue sections from formalin-fixed, paraffin-embedded bone marrow biopsy specimens were processed for immunoperoxidase staining by a variation of a published method.³² Sections on albumin-coated slides were extracted with xylene to remove the paraffin, washed in ethanol, and treated with 1% hydrogen peroxide in methanol to inactivate endogenous peroxidase activity. Sections were rehydrated, treated with 0.1% pronase in Tris buffer, washed in Tris-saline, and exposed to 20% normal rabbit serum or 20% normal swine serum for 30 minutes to decrease nonspecific binding of antibodies. Sections were exposed for one hour to 1:50 dilutions of ascites containing specific monoclonal antibodies or control ascites. Polyclonal rabbit antilysozyme (Dakopatts Antibodies, Accurate Chemical and Scientific Corp, Westbury, NY) was used to examine the lysozyme content of the cells. After washing, the sections were exposed either to peroxidase-conjugated rabbit IgG antimouse immunoglobulin or to peroxidase-conjugated swine IgG antirabbit immunoglobulin (Dakopatts Antibodies, Accurate Chemical and Scientific Corp). The peroxidase reaction was developed with 3,3-

diaminobenzidine (Sigma) and the sections counterstained with hematoxylin. Bone marrow biopsy specimens were reviewed by light microscopy, and the percentage of peroxidase-positive bone marrow cells was determined by four observers. The total percentage of cells that expressed a particular antigen was determined regardless of whether cells appeared to be blastic, more mature myeloid, or nonmyeloid in morphology.

Correlation of antigenic expression and blast transformation. The following, when accompanied by appropriate clinical presentation, was accepted as the definition of the blastic stage of CML: 25% or more blasts in peripheral blood or bone marrow, 40% or more blasts plus promyelocytes in blood, or 50% or more blasts plus promyelocytes in marrow. In addition, the presence of leukemic tumor masses or tissue infiltration with immature leukemic cells was accepted as evidence of extramedullary blastic transformation.

The two-tailed Student's *t* test was used to determine the significance of differences in the percentage of antigen-positive cells in marrow biopsy specimens from different subgroups of patients. Linear regression and correlation analysis were used to assess the significance of the relationship between the percentage of cells expressing a particular antigen and the time from the date of biopsy to the date of blast transformation. The form of the relationship between the two variables was explored with a scatter plot. Three patients included in this analysis had more than one bone marrow biopsy sample obtained 2 months or more prior to blast transformation. Multiple biopsy specimens from the same patient may not be statistically independent; however, there is possible bias in eliminating either early or late observations. Therefore, the data were analyzed by both including these multiple biopsy samples or excluding the early or late biopsy samples from these three patients. Linear regression and correlation analysis were also used to assess the relationship between the percentage of immature cells (myeloblasts and promyelocytes) in bone marrow specimens and the time until blastic transformation and the relationship between the percentage of immature cells and the percentage of cells expressing a particular antigen.

RESULTS

Characteristics of the patient population. Thirty-two patients are included in this study. All patients had the diagnosis of CML made by standard criteria including bone marrow. Two patients were diagnosed prior to transfer of their care to Yale-New Haven Hospital, and peripheral blood counts obtained prior to the initiation of single-agent therapy were not available. None of the patients in this study presented in blast crisis, although two patients had greatly increased blasts plus promyelocytes (40% to 50%) in the bone marrow at time of diagnosis. Both patients were treated with hydroxyurea, and both remain in the chronic phase at 1 and 3 years after diagnosis. Cytogenetic studies were done on all but one patient. Three patients were negative for the Philadelphia chromosome, whereas the remainder were all positive. Three patients had additional chromosomal abnormalities detected at the time of diagnosis. The subpopulation of patients that were Philadelphia chromosome-negative or had additional chromosomal abnormalities at the time of diagnosis is too small for individual analysis. There are 17 females and 15 males, with a median age of 52.7 (range, 25 to 89). The mean time elapsed between the onset of symptoms and diagnosis was 2.5 months. All patients were treated with conventional therapy consisting of single-agent chemotherapy (hydroxyurea or busulfan) during the chronic stage.

Clinical and laboratory features of the 32 cases at the time of diagnosis are shown in Table 1.

Of the 32 patients, 20 (63%) have died due to progression of CML into the blastic or accelerated phase, and 12 (37%) were alive at the last reporting date. The actuarial survival curve for this population (Fig 1) is consistent with other patterns previously described for CML patients.^{2,7-9} Eight patients who entered blast transformation developed chromosomal abnormalities in addition to the Philadelphia chromosome during the course of the disease. In six patients, these changes were detected at the time of blast transformation. Additional chromosome abnormalities were noted 14 months and 5 months prior to blast transformation in the remaining two patients. Chromosomal abnormalities in addition to the Philadelphia chromosome have been noted in three patients who remain in the chronic phase at 64 months, 15 months, and 12 months of follow-up.

Characterization of the monoclonal antibodies and the antigens. Monoclonal antibodies from three hybridoma subclones, PMN13F6 (IgG₁), PMN7C3 (IgG₃), and PMN8C7 (IgG₁) were chosen for this study because they detected antigens that first appear at different stages of neutrophil differentiation. PMN7C3 has been described in detail elsewhere.^{19,20}

The results of an enzyme-linked indirect immunoassay used to quantitate the binding of the monoclonal antibodies to peripheral blood cells are shown in Fig 2. All three monoclonal antibodies were neutrophil specific with no significant binding to mixed mononuclear cells (lymphocytes plus monocytes), monocytes, or erythrocytes. None of the antigens identified by these three monoclonal antibodies were expressed on any cells other than neutrophils and

Table 1. Clinical and Laboratory Features at the Time of Original Diagnosis

	Present	24	75.0

*The percentage of patients within each subcategory is based on the total number of patients for which information regarding that category is known.

Fig 1. Survival curve of all patients included in study from the date of diagnosis.

neutrophil precursors as determined by indirect immunofluorescence labeling followed by cell cytometry. Direct visualization of indirect immunofluorescence-labeled cells confirmed that none of the three antibodies bound to eosinophils, basophils, monocytes, lymphocytes, platelets, or erythrocytes. In addition, using these same techniques, it was determined that all mature, normal neutrophils expressed the antigens detected by PMN13F6 and PMN8C7. A subset of 1% to 3% of neutrophils from some individuals did not express the antigen identified by PMN7C3.

Normal bone marrow biopsy material exposed to monoclonal antibodies PMN13F6, PMN7C3, and PMN8C7 and subsequently labeled by the indirect immunoperoxidase method is shown in Fig 3. There were no peroxidase-positive cells after incubation with control ascites (Fig 3A). PMN13F6 (Fig 3B) bound to all neutrophil precursors in normal marrow. Myeloblasts and all more mature neutrophils were peroxidase-positive when labeled with PMN13F6, whereas islands of erythroid precursor cells and megakaryocytes remained negative. PMN7C3 (Fig 3C) labeled promyelocytes and all more mature neutrophils. PMN8C7 (Fig 3D) bound to metamyelocytes, band forms, and mature neutrophils.

These antibodies detected antigens present in whole cell extracts from normal neutrophils. The antigens were examined after both single-dimension SDS-PAGE (Figs 4 and 5) to determine the molecular weight and IEF focusing followed by PAGE to determine pI (data not shown). PMN13F6

Fig 2. Binding of (□) PMN13F6, (▨) PMN7C3, and (■) PMN8C7 to human peripheral blood cells measured in an indirect enzyme-linked antibody microtiter assay. Binding is expressed as the optical density at 414 nm of the enzyme reaction product. The results shown are the mean with SE of binding to an equal number of neutrophils, mononuclear cells, or erythrocytes from each of three donors.

detected two bands of material with an M_r of 68,000 and 80,000 and a pI of 4.5 to 5.4 when examined by Western blot analysis (Fig 4). PMN7C3 recognized a myeloid-specific carbohydrate epitope present on a number of neutrophil glycoproteins including the group of related leukocyte membrane glycoproteins associated with the C3bi receptor complex.²⁰ PMN7C3 appeared to detect two broad, high-molecular weight bands (Fig 4) on Western blot analysis of whole cells. PMN8C7 detected a membrane antigen that consists of a single band with an M_r of 14,000 to 16,000 and a pI of 7.8 to 8.3 (Fig 5).

Expression of antigens on bone marrow cells from patients with CML. Analysis of antigen expression on bone marrow biopsy specimens from the 20 patients in the study who have progressed to blast crisis is shown in Table 2. Ten of these bone marrow biopsy samples were obtained from the patients at time of the initial diagnosis of CML and prior to single-agent therapy. An example of bone marrow biopsy material obtained from a patient at the time of diagnosis and labeled with PMN13F6 is shown in Fig 6A. The marrow is hypercellular, and the majority of cells expressed the antigen detected by PMN13F6 antibody. There was a similar increase in antigen-positive cells with PMN7C3 and PMN8C7 at the time of diagnosis of CML as compared with antigen-positive cells in normal bone marrows.

The remainder of the biopsy specimens represented in Table 2 were obtained at various stages throughout the chronic phase or blastic phase. An example of a bone marrow biopsy sample obtained at the time of blastic transformation and labeled with PMN13F6 is shown in Fig 6B. The marrow was occupied predominately by cells that do not express the antigen. There was a similar pattern of loss of expression of the antigens identified by PMN7C3 and PMN8C7 in bone marrow biopsy specimens obtained at the time of blast crisis.

In all cases with multiple sequential biopsy samples, except one, there was a decrease in the percentage of cells expressing the antigens detected by these antibodies as the disease progressed to the terminal stage (Table 2). Loss of antigen expression occurred in both mature- and immature-appearing myeloid cells (Fig 6), and loss of antigen expression occurred in both lymphoid (terminal deoxynucleotidyl transferase [TdT]-positive) and myeloid (TdT-negative) blast transformation (Table 2). The one case that did not exhibit a decrease in the percentage of cells expressing these antigens (case number 8) was a patient with extramedullary blast transformation diagnosed from axillary lymph node biopsy material.

The percentage of binding of PMN13F6 to all bone marrow biopsy specimens obtained at the time of blast transformation, excluding the patient with extramedullary blast transformation, ranged from no binding to 40% binding (mean $\pm$ SD, $14\% \pm 12\%$), and including the patient with extramedullary blast transformation, the mean percentage of binding was $20\% \pm 25\%$ (Table 3). Bone marrow biopsy specimens obtained from patients more than 2 months but less than 1 year prior to the time of blast transformation were 50% to 90% positive for PMN13F6 (mean, $68\% \pm 15\%$), whereas those obtained 1 year or more prior to blast transfor-

Fig 3. Sections of a normal bone marrow biopsy sample labeled with the immunoperoxidase method using control mouse ascites-derived immunoglobulin (3A), PMN13F6 (3B), PMN7C3 (3C), or PMN8C7 (3D). The peroxidase reaction product is brown; nuclei are stained purple. Cytoplasm is not counterstained to avoid obscuring the peroxidase stain. In Fig 3A (control), there are no peroxidase-positive cells. PMN13F6 incubation, Fig 3B, followed by immunoperoxidase resulted in labeling of the myeloblasts as well as all the more mature neutrophil cells and precursors. PMN7C3, Fig 3C, detects an antigen present on promyelocytes and all more mature neutrophils; PMN8C7 detects an antigen that first appears at the metamyelocyte level.

mation were 50% to 95% positive for PMN13F6 (mean, $81\% \pm 12\%$).

Sixteen bone marrow specimens from 12 patients who have not yet entered the accelerated or blastic phase of disease were examined for antigenic expression of normal myeloid antigens. The median follow-up is 30 months (range, 4 to 106 months), and the mean binding for PMN13F6 is $82\% \pm 9\%$ (Table 3).

The two-tailed Student's *t* test was used to determine the statistical significance of differences in the percentage of antigen-positive cells in biopsy samples obtained at different time intervals. The difference between the mean of PMN13F6-positive cells from bone marrow biopsy material obtained at the time of blast transformation, even including the patient with extramedullary blast transformation in the evaluation, was highly significant compared with the means of all other categories ($P < .001$). The mean of PMN13F6-

positive cells from biopsy material obtained 2 months to 1 year prior to blast transformation was less significant compared with the mean of positive cells from bone marrow specimens taken more than 1 year before blast crisis ($P < .06$) but was significant compared with the mean of PMN13F6-positive cells from patients who have not yet entered blastic transformation ($P < .01$). The difference between the mean of PMN7C3- ($19\% \pm 25\%$) and PMN8C7 ($13\% \pm 25\%$)-positive cells from biopsy specimens at the time of blast transformation was highly significant compared with the means of all other categories ($P < .001$). The mean of PMN7C3- and PMN8C7-positive cells from biopsy material obtained 2 months to 1 year prior to blastic transformation was significant compared with the means of positive cells from biopsy samples taken more than 1 year before blast crisis ($P < .05$).

||Bone marrow biopsies done after transformation to blast crisis and after aggressive chemotherapy (not included in statistical analysis).

percentage of bone marrow cells expressing the PMN13F6 antigen and the time to blast transformation is shown in Fig 7. Only bone marrow biopsy specimens obtained more than 2 months prior to blastic transformation are included in this evaluation ($n = 19$) in order to determine the value of antigen expression as a predictor of blastic transformation. Regression and correlation analysis determined that the correlation coefficient was significant ($r = .6533$, $P < .005$) for PMN13F6. As noted in Materials and Methods, three patients had more than one biopsy sample obtained prior to

blast transformation. If the multiple observations from these three patients were excluded from the analysis, as described in Materials and Methods, the correlation coefficient was still significant ($P < .05$). The correlation coefficient for the relationship between the percentage of cells expressing the antigen detected by PMN7C3 from all specimens prior to blastic crisis and the time until blast transformation was $r = .6304$ ($P < .005$), and for the relation of PMN8C7 binding to time of blast transformation it was $r = .5215$ ($P < .05$).

Regression and correlation analysis of bone marrow samples obtained within 1 year of blastic transformation indicated a significant relationship between the percentage of PMN13F6-positive cells and the time to blastic crisis ($r = .7739$, $P < .02$). Because of the small number of bone marrow biopsy specimens ($n = 8$), further analysis of this category was not done.

Regression and correlation analysis of the relationship between antigen-positive cells and time to blastic transformation was also determined for all biopsy material from patients who have progressed ($n = 31$) including those samples obtained at the time of transformation (time 0). The correlation coefficient was highly significant ($P < .001$) for the relationship between expression of all three antibodies and time of blastic transformation (PMN13F6, $r = .8167$; PMN7C3, $r = .7665$; PMN8C7, $r = .7436$).

The relationship of the percentage of cells positive for each of the three antibodies and the percentage of myeloblasts and promyelocytes present in each bone marrow sample obtained prior to blastic transformation was analyzed. There was a negative correlation between the percentage of cells reactive with PMN13F6 and the percentage of immature cells ($r = -.7961$, $P < .001$). Analysis of the relationship between the percentage of cells positive for PMN7C3 and percentage of immature cells resulted in a correlation coefficient of $r = -.5144$ ($P < .05$). There was no significant relationship between PMN8C7 positivity and the number of immature cells ($r = -.3145$, $P < .20$) by correlation and regression analysis.

Regression and correlation analysis of the percentage of immature cells present in bone marrow biopsy material obtained prior to blastic crisis and the time until blastic crisis determined a significant correlation coefficient of $r = -.6206$ ($P < .005$).

Three bone marrow samples from two patients were examined after aggressive combination chemotherapy following blastic transformation. Therapy consisted of daunorubicin, cytosine arabinoside, and 6-thioguanine. Bone marrow biopsy specimen 3 from patient 5 (Table 2) was obtained 6 weeks after beginning aggressive therapy and was interpreted as consistent with a return to the chronic phase. The patient relapsed 4 weeks later and expired within 1 week. Bone marrow biopsy specimen 3 from patient 6 was obtained 1 month after the beginning of aggressive therapy and was interpreted as a 50% decrease in blasts from the examination done at the time of blastic crisis. A subsequent bone marrow biopsy sample (no. 4) demonstrated repeated antigenic loss 4 weeks later when the disease progressed despite therapy. This patient failed to respond to additional aggressive chemotherapy and died 2 weeks after the last biopsy.

Fig 6. Bone marrow biopsy specimens obtained from patients at the time of diagnosis of CML (6A) and blastic crisis (6B). Both were labeled by using the immunoperoxidase method using PMN13F6, the earliest-appearing myeloid antigen used in this study. In Fig 6A (diagnosis) the marrow is hypercellular, and the majority of cells express the antigen detected by PMN13F6. In Fig 6B (blastic crisis), the marrow shows predominantly immature cells that, although myeloid, do not express the PMN13F6 antigen. In addition, some mature myeloid cells failed to express the PMN13F6 antigen.

Intracytoplasmic lysozyme was examined in all bone marrow biopsy material by using the antilysozyme antibody. Myeloid cells at various stages of differentiation, from promyelocytes to segmented forms, were strongly positive for intracytoplasmic lysozyme. Blast cells from patients at all stages showed great variability in amount of lysozyme detected.

DISCUSSION

Studies by several groups have examined the prognostic significance of disease features recorded at the time of diagnosis.⁷⁻¹¹ These include the presence or absence of the Philadelphia chromosome, spleen size, percentage of circulating blasts, major abnormalities of erythropoiesis or platelet production, and basophilia or eosinophilia. The Philadelphia chromosome has prognostic significance as an indicator of survival but is not useful for predicting the timing of blast transformation for an individual patient.^{9,14,16,17} A high proportion of myeloblasts plus promyelocytes in peripheral

blood or bone marrow at diagnosis have been shown to indicate a shortened overall survival time.⁷⁻¹⁰ However, again these criteria are not reliable predictors of the time from diagnosis to blast transformation for an individual patient.

A number of signs acquired during the clinical course of CML are suggestive of impending transformation to the blastic stage.¹²⁻¹⁵ The appearance of blastic crisis is often associated with chromosomal aberrations in addition to the Philadelphia anomaly.¹⁴ Additional chromosomal abnormalities were found in cells from some subjects included in our study. In the majority of cases, these were not detected until obvious blastic transformation. Chromosomal abnormalities often occur too late in the course of the disease to be of value for the prediction of the time to blastic crisis. The appearance of two Philadelphia chromosomes during the course of the disease signals impending blastic crisis,¹⁷ but this event is too rare to be predictive in the majority of patients.^{14,17}

Table 3. Percentage (Mean $\pm$ SD) of Bone Marrow Cells Expressing Myeloid Antigens at Different Intervals Prior to Blast Crisis, at Blast Crisis, or From Patients Who Remain in the Chronic Phase

Time to BT	Number of Biopsies	Mean PMN13F6 (%)	Mean PMN7C3 (%)	Mean PMN8C7 (%)
Remain in chronic phase				
4 mo-106 mo (median, 30)	16	82 $\pm$ 9	62 $\pm$ 14	68 $\pm$ 14
13 mo-49 mo Prior to BT (median, 23)	11	81 $\pm$ 12	71 $\pm$ 5	64 $\pm$ 15
2 mo-12 mo (median, 5.5)	8	68 $\pm$ 15	51 $\pm$ 17	46 $\pm$ 18
Blast crisis without extramedullary	11	14 $\pm$ 12	11 $\pm$ 10	6 $\pm$ 6
Blast crisis with extramedullary	12	20 $\pm$ 25	19 $\pm$ 25	13 $\pm$ 25

Abbreviation: BT, blast transformation.

Fig 7. A scatter diagram indicating the relationship between the percentage of bone marrow cells expressing the PMN13F6 antigen and time from bone marrow biopsy to blast transformation. Time is plotted as $\log_{10}$. Only bone marrow biopsy specimens obtained more than 2 months prior to blast transformation are included in this analysis to determine the prognostic value of antigen expression for the prediction of blast transformation. The solid line represents conventional linear regression. Regression and correlation analysis determined that the correlation coefficient was $r = .6533$, which is significant at $P < .005$.

The appearance of increased numbers of myeloblasts and promyelocytes in the peripheral blood or bone marrow is often used as a sign of impending blastic crisis. Immature cells in the peripheral blood, used as a single sign, identified 27% of patients who entered the terminal phase within 6 months.¹³ Marked oscillations in the number of peripheral early myeloid cells limit the usefulness of this criterion.¹⁴ Since changes in the bone marrow may antecede those in the peripheral blood, bone marrow may be a better reflection of disease status. In our study, the relationship between the percentage of immature cells and the time to blastic crisis was significant ($P < .005$) and similar to the relationship between the percentage of antigen-positive cells and the time to transformation. Both sets of observations, however, were based upon a group of patients evaluated retrospectively and are therefore limited. Predictions based upon changes within a group, particularly one laboratory parameter, may not reflect individual outcomes. Thus, currently there is no universally accepted method for predicting the timing of blast transformation, and additional criteria are needed to provide predictive indicators.

Antigen expression on blood cells from patients with CML have been examined at the time of blastic transformation.³³⁻³⁶ Gallin et al, in association with our laboratory, previously noted that loss of an antigen present on the majority of mature peripheral neutrophils is associated with progression to the blastic phase of CML.³⁵ In that study, PMN7C3, one of the antibodies also used in this study, had variability of expression in neutrophils from CML patients at the time of blast crisis, but a severe deficiency of PMN7C3 was not noted. The difference between these findings and the current study is presumably due to analysis of peripheral cells, which are more mature, v bone marrow cells, which are more immature.

Griffin and coworkers, using a panel of monoclonal antibodies that recognize differentiation antigens of normal myeloid, erythroid, megakaryocytoid, and lymphoid cells, suggested that determination of antigenic phenotypes at blast crisis may provide clinically useful information for CML treatment protocols.³⁶ In that study leukemic cells from two thirds of 30 CML patients in blast crisis expressed no myeloid antigens when probed with a panel of monoclonal antibodies. Leukemic cells from the remaining one third of patients expressed an antigen associated with myeloid precursor cells.³⁷ Only one patient's cells also strongly expressed antigens found on more mature myeloid cells. These data are in agreement with our data that clearly show a deficiency in expression of some myeloid antigens at the time of blastic transformation.

We have not directly compared PMN13F6, PMN7C3, and PMN8C7 monoclonal antibodies with all other antibodies that have been used to investigate myeloid antigen expression in CML cells. However, PMN13F6 and PMN8C7 appear to be unique antibodies that recognize antigens with biochemical characteristics that have not previously been described. PMN7C3, which has been described in detail previously, binds to the C3bi receptor complex.

The present study demonstrates that there is a highly

significant loss of certain myeloid antigens on bone marrow cells from patients with CML at the time of blastic transformation compared with bone marrow cells examined at the time of diagnosis or during the stable phase. Furthermore, this loss appears to be a progressive loss with a significant correlation between expression of some myeloid antigens and time until development of blastic transformation. The data indicate that the loss of myeloid antigen expression may extend over many months rather than major antigenic changes that occur only at the time of blast crisis.

The progressive loss of myeloid antigen expression in CML is not strictly a function of lineage specificity. Antigen loss occurred in both myeloid (TdT-negative) and lymphoid (TdT-positive) blast transformation. The loss of myeloid antigen expression is also not strictly a function of differentiation specificity. Mature cells, in some cases, failed to express the antigens detected by these antibodies. PMN8C7 identifies an antigen that first appears at the metamyelocyte stage of differentiation and persists throughout maturation. There should be a significant relationship between the loss of PMN8C7 reactivity and morphology if progressive loss of this antigen were a function of increased numbers of immature cells. However, there was no correlation between the percentage of cells that expressed or failed to express the PMN8C7 antigen and the percentage of immature cells ($P < .20$). Even more intriguing is the highly significant, inverse relationship between the percentage of cells positive for PMN13F6, which identifies an antigen present throughout differentiation, and the percentage of immature cells. If antigen expression were simply a reflection of morphology, the percentage of PMN13F6-positive cells should remain constant or increase in parallel to the percentage of myeloid cells, regardless of the stage of differentiation.

Despite these observations and the suggested conclusions, speculation is warranted that lineage specificity, differentiation specificity, or both may be involved to some extent in the process of antigenic loss in CML. The clonal origin of the malignancy in CML has been well documented,¹ and it is known that the cell of origin is an early hematopoietic progenitor that is capable of giving rise to not only myeloid cells but also erythroid cells, megakaryocytes, monocytes, and lymphocytes. By conventional morphology and cytochemical analysis, the malignant cells present at blast transformation are recognized as myeloid blasts in 50% to 60% of the cases.¹⁵ Lymphoblast morphology occurs at the time of blast transformation in about one third of patients, usually involving both B cell lineage,^{38,39} and T cell lineage.⁴⁰⁻⁴² In addition, megakaryoblastic and monoblastic blast transformations are known to occur,^{33,43} and it has been suggested that erythroid blast crisis may occur much more frequently than previously recognized.⁴⁴ Thus, myeloid markers may be lost as the disease progresses due to the emergence of increased numbers of cells that are of nonmyeloid lineages. With improved methods of detection, features associated with two or more lineages have been shown to occur during blast transformation.^{35,36,39,40,44-46}

CML blast cells may represent an earlier or undifferentiated stage of maturation compared with the level of differ-

entiation at which a particular antigen is normally expressed. CML blasts may not express PMN13F6 antigen because the blasts are at a stage of differentiation preceding the normal appearance of this myeloblast antigen. Loss of the antigen detected by PMN13F6 was associated with the emergence of increased numbers of immature cells, but these cells were at a morphological level of differentiation at which there is expression of the antigen normally. Thus, antigenic expression during differentiation in CML cells is incongruent with morphological maturation. CML cells, which may appear similar to their normal counterparts at the same level of differentiation, clearly have abnormal antigenic patterns due to either selective expression or lack of expression of some enzymes or surface markers. Thus the highly significant, inverse relation between the percentage of cells expressing the antigen identified by PMN13F6 and the percentage of immature cells may be due to the emergence of abnormal immature cells, the identification of which is made easier by antigenic analysis.

In our study we did not separate the effects of expansion of nonmyeloid lineages, increases in blast cells, or selective loss of markers as a cause of antigen loss. The decision to ignore cell type in relation to antigen expression followed extensive analysis of all marrows with respect to various populations of cells and their contribution to overall cellularity. The myeloid elements and/or blast cells constituted the majority of the total marrow population in all CML biopsy specimens examined, and differential evaluation of nonmyeloid and nonblastic elements did not appear to contribute significantly to the understanding of antigen expression. Determination of antigen expression as the total percentage of cells that were positive for PMN13F6, PMN7C3, or PMN8C7 binding regardless of whether the cells appeared to be blastic, more

mature myeloid, or nonmyeloid in morphology may have enhanced the ability to demonstrate a correlation of antigen loss to blast transformation over a period of time. In addition, the percentage of the entire cell population that expresses or fails to express myeloid antigens in combination with morphological analysis of the percentage of immature v mature cells may provide better prognostic indicators than either variable alone.

The ability to determine the probability of blast transformation occurring within a certain time period would aid in deciding whether to delay or proceed with bone marrow transplantation. The increasingly optimistic results obtained with bone marrow transplantation justify additional studies regarding the use of antigen markers as indicators of the timing of blast transformation. In addition, the reexpression of normal neutrophil antigens after treatment-induced remissions suggests that monitoring antigenic expression may be useful in assessing response to therapy. The ability to predict impending or early blastic transformation during the chronic stage would provide a method to identify those patients who are at high risk of death and who would therefore be suitable candidates for earlier aggressive therapy prior to the development of overt blast transformation or for new, unproved therapeutic protocols. A prospective study with a larger number of patients and bone marrow biopsy samples performed at predetermined regular intervals is necessary to confirm the usefulness of myeloid antigen expression in combination with other indicators.

Low Molecular Weight B Cell Growth Factor Induces Proliferation of Human B Cell Precursor Acute Lymphoblastic Leukemias

By Bernhard Wörmann, Shashikant R. Mehta, Abby L. Maizel, and Tucker W. LeBien

Experiments were conducted to determine the effect of low mol wt B cell growth factor (L-BCGF) on B cell precursor acute lymphoblastic leukemia (ALL). L-BCGF induced a significant increase in ^3H -TdR incorporation in 28 of 37 bone marrow aspirates from patients with B cell precursor ALL, with stimulation indices ranging from 2 to 129. Fluorescence-activated cell sorting confirmed that in five of seven patients the common acute lymphoblastic leukemia antigen (CALLA)/CD10 positive leukemic cells

were responding directly to L-BCGF. L-BCGF was capable of inducing, in some patients, an increase in absolute viable cells and could also induce colony formation in vitro. The response of B cell precursor ALL was not attributable to β IL 1, IL 2, or γ interferon. These results indicate that the majority of B cell precursor ALL undergo a proliferative response to L-BCGF, suggesting a regulatory role for this lymphokine in the growth of B cell precursors.

© 1987 by Grune & Stratton, Inc.

OVER THE PAST several years a number of lymphokines have been described that influence the proliferation and differentiation of human and murine B cells at various stages of development.¹⁻³ In humans these include low mol wt B cell growth factors (L-BCGF),^{4,5} high mol wt BCGF,⁶ B cell stimulatory factor 1 (BSF-1)/interleukin 4 (IL 4),⁷ B cell differentiation factor (BSF-2),⁸ B cell activation factor,⁹ pre-B cell growth factor,¹⁰ B cell inhibitory factor,¹¹ interleukin 2 (IL 2),¹²⁻²³ and gamma interferon.²⁴⁻²⁶ Analysis of the biochemical and structural characteristics of these lymphokines, their role in B cell activation, and the characterization of their target cells is currently an area of active investigation.

The 12 kd human L-BCGF is a T cell-derived lymphokine that acts on preactivated B cells, ie, activated with anti-IgM antibody.²⁷ L-BCGF is probably derived from a 60-kd cytosolic precursor protein,²⁸ and L-BCGF has recently been purified to a single band on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis.²⁹ Studies on L-BCGF-dependent B cell lines and activated B cells show the presence of $\sim 10^4$ high affinity and $\sim 3.5 \times 10^4$ low affinity receptors.³⁰ In experiments using neoplastic B cells, Ford et al³² have demonstrated a direct proliferative effect of L-BCGF on hairy cells³¹ and on cells from different B cell non-Hodgkins' lymphomas.

The factors influencing the proliferation of malignant

human B cell precursors are poorly understood. Experiments using colony assays for growth of B cell precursor acute lymphoblastic leukemias (ALL) suggest a role of soluble growth factors either provided by leukocyte feeder cells³³ or present in leukocyte-conditioned medium,^{34,35} and Töuw et al³⁴ suggested that one of the factors was IL 2. As part of an effort to examine factors influencing the growth of B cell precursor ALL (also termed "common" ALL or non-T/non-B ALL), we herein report on experiments using L-BCGF. Our results indicate that the majority of B cell precursor ALL undergo a proliferative response to this lymphokine.

MATERIALS AND METHODS

Leukemic specimens. Bone marrow aspirates from 37 patients with newly diagnosed B cell precursor ALL were analyzed. All specimens were obtained through the Cell Marker Laboratory, Department of Laboratory Medicine and Pathology, University of Minnesota. Only aspirates with >90% blasts were included. Diagnosis of B cell precursor ALL was based on standard morphological, cytochemical, and immunologic criteria. All samples expressed at least two of the three B cell-associated antigens p24/CD9,³⁶ common acute lymphoblastic leukemia antigen (CALLA)/CD10,³⁷ and gp42/CD24.³⁸ No sample contained more than 5% T cells based on expression of CD5³⁹ and CD7⁴⁰; more than 5% normal, mature B cells based on expression of surface Ig; more than 5% myeloid cells based on expression of CD13⁴¹; or more than 5% monocytes based on expression of CD11.⁴² Eight of the 37 bone marrow aspirates had been cryopreserved in liquid nitrogen for two to 24 months prior to analysis. We have analyzed the influence of freezing and thawing on the response to L-BCGF by comparing the L-BCGF response of seven noncryopreserved specimens to the L-BCGF response after having frozen and thawed the same specimens. Only samples with greater than 85% viable cells after thawing were analyzed, and no significant differences in the response to L-BCGF were observed (data not shown).

Proliferation assay. Bone marrow aspirates were separated on Ficoll-Hypaque (FH) gradients. Two $\times 10^5$ interface cells were incubated in 96 well flat-bottom plates (3596, Costar) in RPMI 1640 containing 10% vol/vol fetal bovine serum (FBS; Gibco Laboratories, Grand Island, NY), in the presence or absence of various concentrations of L-BCGF (Cellular Products Inc, Buffalo, NY). All experiments were set up in triplicate. Cells were harvested after 90 to 96 hours, except in the time course experiments.

Cell proliferation was determined by:

1. ^3H -TdR incorporation: ^3H -TdR (Amersham, Arlington Heights, IL; specific activity-20 Ci/mmol) was diluted in RPMI 1640/10% FBS and added at a

concentration of 1 μ Ci per well for the last eight (patients 9 to 37 in Table 1) or 16 hours (patients 1 to 8). The cells were harvested on glass fiber filters using a cell harvester (M-24, Brandel, Gaithersburg, MD). The filters were dried for at least four hours, and ^{3} H-TdR incorporation was measured by liquid scintillation spectrometry. Stimulation indices are presented as the ratio of ^{3} H-TdR incorporated into cells incubated in the presence of L-BCGF compared to ^{3} H-TdR incorporated into cells incubated with no L-BCGF. We compared the results of 2-, 4-, 8-, and 16-hour incubations with ^{3} H-TdR. As no significant differences in the stimulation indices were observed between the eight- and the sixteen-hour incubations, we used the eight-hour incubation beginning with patient 9 (Table 1).

*Leukemic cells were cultured in the presence or absence of 10% vol/vol L-BCGF for 96 hours and were pulsed with ^{3} H-TdR for the final eight (patients 9 to 37) or 16 (patients 1 to 8) hours.

†Stimulation index: Ratio of ^{3} H-TdR incorporation in the L-BCGF-treated cells compared to controls treated with no L-BCGF.

‡Mean cpm $\pm$ SD of ^{3} H-TdR incorporation in triplicate cultures.

2. Cell count: Cells from triplicate wells were vigorously pipetted and pooled. The wells were checked under an inverted microscope to ensure that all cells had been removed. Cell viability and absolute cell counts were analyzed by trypan blue exclusion.
3. Colony assay: One $\times 10^5$ leukemic bone marrow cells were suspended in 1 mL of RPMI 1640 containing 25% FBS, 5×10^{-5} mol/L 2-mercaptoethanol, 0.9% methylcellulose in the presence or absence of 10% vol/vol L-BCGF. The cells were cultured in 35-mm petri dishes at 37°C in a humidified 5% CO₂ atmosphere and analyzed by inverted microscopy after ten days.

Lymphokines. Partially purified L-BCGF was obtained from Cytokine Technology, Buffalo, NY. L-BCGF did not contain detectable IL 2 activity based on the inability to support the growth of IL 2-dependent CTLL-20 cells (assay generously conducted by Dr Siew-Lin Wee, Immunobiology Research Center, University of Minnesota). Highly purified L-BCGF was isolated as previously described.³⁰ Recombinant beta interleukin 1 (β IL 1), recombinant interleukin 2 (IL 2), and recombinant gamma interferon (gamma IF) were purchased from Genzyme Corporation, Boston.

Sorting of CALLA/CD10 positive cells. Bone marrow aspirates were used for cell sorting. In seven of eight samples the cells had been cryopreserved until the results of the effect of L-BCGF on the fresh bone marrow aspirates were known. The cells were thawed from liquid nitrogen, washed twice in fluorescence buffer (PBS containing 2.5% FBS and 0.02% sodium azide), stained with the anti-CALLA/CD10 monoclonal antibody (MoAb) BA-3 for 30 minutes at 4°C, washed once in fluorescence buffer, stained with fluorescein isothiocyanate (FITC) goat antimouse Ig (Cappel Worthington Biochemicals, Malvern, PA, dilution 1:20) for 30 minutes, and washed three times. Three- 10×10^6 CALLA/CD10 positive cells were then sorted on a FACS IV (Becton Dickinson, Mountain View, CA). Forward and 90° light-angle scatter were used to gate on the viable leukemic cells. Only cells exhibiting fluorescence intensity clearly above background were sorted into the CALLA/CD10 positive fraction. These cells constituted 85% to 90% of the leukemic cell population. To exclude the potential influence of BA-3 on the in vitro L-BCGF response, we incubated and stained cells with BA-3 and FITC goat antimouse Ig, but did not sort them.

Statistics. For analysis of the differences between L-BCGF stimulated and unstimulated cells we used the student's *t* test on a log scale. Results with *P* < 0.05 were considered statistically significant.

RESULTS

Response of B cell precursor ALL bone marrow aspirates to L-BCGF. We initially analyzed the effect of L-BCGF on the incorporation of ^{3} H-TdR in FH-isolated cells from bone marrow aspirates of 37 patients with B cell precursor ALL. The results obtained when cells were stimulated with 10% vol/vol L-BCGF are presented in Table 1. In 28 of the 37 patients (74%) a significant increase in ^{3} H-TdR incorporation was observed. The individual responses varied widely, with stimulation indices ranging from 2 to 129 and 12 of the patients having a stimulation index >10.

In 15 of 17 responding patients the effect of different concentrations of L-BCGF was studied. The results shown in Fig 1 underscore the variable sensitivity to L-BCGF. Cells from 5 of 15 patients showed a significant increase of ^{3} H-TdR incorporation over background in the presence of only 1% vol/vol L-BCGF. Cells from four patients required

Fig 1. Variability in response of FH-isolated bone marrow cells from 15 patients with B cell precursor ALL who responded to L-BCGF. Cells were incubated with increasing concentrations of L-BCGF or no L-BCGF for 96 hours and pulsed with ^3H -TdR for the final eight or 16 hours. Data show the cumulative number of patients that, at a given concentration of L-BCGF, exhibited a statistically significant increase ($P < 0.05$) in ^3H -TdR incorporation compared to the controls, as determined by the student's t test.

5% vol/vol L-BCGF, and the remaining six patients required 10% vol/vol L-BCGF to show a response. CALLA/CD10 positive cells were sorted from three patients, and the L-BCGF response of the sorted cells paralleled the results obtained with unsorted cells (data not shown). L-BCGF concentrations of $>15\%$ vol/vol inhibited ^3H -TdR incorporation in B cell precursor ALL.

Response of CALLA/CD10 positive leukemic cells to L-BCGF. To confirm that the L-BCGF response was not due to ^3H -TdR incorporation by nonleukemic cells, we isolated CALLA/CD10 positive leukemic cells from seven patients by cell sorting and examined their response to L-BCGF. We chose this approach, since CALLA/CD10 is not expressed on surface Ig positive normal B cells, and $>90\%$ of cells in these aspirates were CALLA/CD10 positive. Cells stained with BA-3 and FITC goat antimouse Ig, but not sorted, were used to control for the effects of surface-bound antibody on L-BCGF-induced ^3H -TdR incorporation. The results in Table 2 indicate that in five of seven patients (Nos. 7, 9, 13, 15, and 18), the L-BCGF response of CALLA/CD10 positive cells essentially recapitulated the L-BCGF response of stained, unsorted cells. In patient No. 17 a twofold increase in ^3H -TdR incorporation was observed, but this was not statistically significant. In patient No. 8 a comparison of stained, unsorted cells (Table 2) with cells not stained with BA-3 and FITC goat antimouse Ig (Table 1)

clearly shows that leukemic cell-bound antibody did not influence the response to L-BCGF. Failure of this patient's CALLA/CD10 positive leukemic cells to respond could be attributable to (1) cell damage during the sorting procedure, (2) ^3H -TdR incorporation by surface Ig positive, CALLA/CD10 negative normal B cells in the bone marrow aspirate, or (3) dependency on accessory cells such as monocytes or T cells. In patient No. 7 the L-BCGF response of CALLA/CD10 positive cells was $\sim$ tenfold higher than in the stained, unsorted bone marrow aspirate, suggesting an inhibitory effect mediated by factors produced by contaminating normal cells. To formally exclude this as an explanation for the nonresponding leukemic samples, we sorted CALLA/CD10 positive cells from one nonresponding patient (No. 1 in Table 1) and examined their response to L-BCGF. These sorted CALLA/CD10 positive cells did not respond to L-BCGF (Table 2).

Cell proliferation studies. Time sequence studies of ^3H -TdR incorporation and absolute viable cell counts of the CALLA/CD10 positive leukemic cells were conducted on several patients. In the first patient (Fig 2A, patient No. 7 in Table 1) an increased incorporation of ^3H -TdR was seen after day 2 and continued through day 6 in the presence of L-BCGF. The cell count in the L-BCGF-treated cultures dropped over the first three days to $300 \times 10^3/\text{mL}$ on day 3 and then increased slightly to $400 \times 10^3/\text{mL}$ on day 6 (Fig 2B). The cell count in the control wells plateaued at $150 \times 10^3/\text{mL}$ from days 3 to 6. In the second patient (Fig 2C, No. 18 in Table 1) ^3H -TdR incorporation steadily increased from day 2 to day 6 in the L-BCGF-treated cultures. The cell number remained stable from day 2 to day 6 in the presence of L-BCGF, whereas the cell number in the controls dropped to 10% of the starting concentration by day 6 (Fig 2D). In the third patient (Fig 2E, No. 15 in Table 1) an increase in ^3H -TdR incorporation in L-BCGF-treated cultures compared to controls was detectable on day 1 and peaked on day 3. The initial cell loss was substantial in the L-BCGF-treated cultures, dropping to $260 \times 10^3/\text{mL}$ within the first 24 hours followed by an increase to $530 \times 10^3/\text{mL}$ by day 3 (Fig 2F). In a fourth patient (No. 37 in Table 1) we analyzed absolute viable cell numbers over a longer period of time (Fig 3). This patient's leukemic cells underwent a rigorous proliferative response to L-BCGF, with the absolute

Fig 2. Time sequence of $^3\text{H-TdR}$ incorporation (A, C, E) and absolute viable cell numbers as determined by trypan blue exclusion (B, D, F) of CALLA/CD10-positive leukemic cells after incubation in 10% vol/vol L-BCGF (—●—) for zero to six days. Control cultures (---○---) did not contain L-BCGF. The $^3\text{H-TdR}$ incorporation data points represent the mean of triplicate values ± 1 SD (horizontal bars). The absolute cell number data points were derived by pooling triplicate wells and dividing the total viable cell count by three. A and B are patient No. 7; C and D are patient No. 18; and E and F are patient No. 15 from Table 1. Note that the ordinates in A and C are on a log scale.

viable cell number doubling at five days and tripling at ten days, compared to day 0. Note that control cells cultured with no L-BCGF dropped in absolute viable cell number.

We also used a colony assay to examine the *proliferative* response to L-BCGF. When cells from patient No. 36 (Table 1) were plated in the presence of L-BCGF, dramatic colony formation was observed by day 10 (Fig 4A), whereas no colony formation was observed in cells cultured without L-BCGF (Fig 4B). The cloning efficiency for the L-BCGF cultures was 8.3% for cluster formation (>10 cells) and 0.4% for colony formation (>50 cells). The phenotype of the colony-forming cells was identical to the original, uncultured cells ($\text{CD}9^+$, $\text{CD}10^+$, $\text{CD}24^+$, and cytoplasmic and surface IgM^-).

Fig 3. Cell growth of B cell precursor ALL (No. 37 in Table 1) in response to L-BCGF. Cells were incubated in the presence (—●—) or absence (---○---) of 10% vol/vol L-BCGF and quantitated at different time points. Cell viability was assessed by trypan blue dye exclusion.

Response of B cell precursor ALL to highly purified L-BCGF and other recombinant lymphokines. To confirm that the response of B cell precursor ALL was not attributable to a contaminant in the partially purified commercial product, we compared the response of a B cell precursor ALL to partially purified and highly purified L-BCGF. Leukemic cells from patient No. 36 (Table 1) had been maintained in partially purified L-BCGF for 20 days, followed by L-BCGF-free medium for 25 days. Under L-BCGF-free conditions the cells remained viable and showed little change in concentration. Results in Table 3 show the response of these cells to the two sources of L-BCGF. It is very apparent that 0.1% vol/vol and 1.0% vol/vol *highly purified* L-BCGF-triggered $^3\text{H-TdR}$ incorporation in the leukemic cells, comparable to the partially purified L-BCGF. Since units of activity are not defined in these preparations, it is not possible to directly equate them. Higher concentrations of highly purified L-BCGF (10% vol/vol) inhibited $^3\text{H-TdR}$ incorporation.

We examined the $^3\text{H-TdR}$ incorporation of B cell precursor ALL to increasing concentrations of $\beta\text{IL 1}$, IL 2, gamma IF, and L-BCGF. Whereas the leukemic cells exhibited a dose-dependent response to partially purified L-BCGF, no response occurred to $\beta\text{IL 1}$ (0.1 to 10 units/mL), IL 2 (10 to 1,000 units/mL), or gamma IF (10 to 10,000 units/mL; data not shown).

DISCUSSION

The growth factors and their receptors, which mediate the proliferation of B cell precursor ALL, are poorly understood. Prior studies reporting colony formation by B cell precursor

Fig 4. Colony formation of a B cell precursor ALL (No. 36 in Table 1) cultured in the presence (Fig 4A) or absence (Fig 4B) of 10% vol/vol L-BCGF for ten days. Cells from this patient were initially cultured in the presence of L-BCGF for 20 days. The cells were then split, and half of them were maintained in medium containing 25% fetal bovine serum (FBS) with no L-BCGF for 25 days. Under these conditions the cells remained viable and the cell number was stable. The phenotype prior to the colony formation experiment was unchanged as compared to the initial analysis (CD9 positive, CD10/CALLA positive, CD24 positive, negative for surface and cytoplasmic IgM). No colony formation was seen in the cultures without L-BCGF (Fig 4B).

ALL have shown a dependency on soluble factors provided by leukocyte feeders³³ or leukocyte-conditioned medium.^{34,35} Although the biochemical nature of the required growth factors were not elucidated, Touw et al³⁴ showed that B cell precursor ALL colony formation was enhanced by recombinant IL 2 in some cases.

In the present study we have provided evidence that ~75% of B cell precursor ALL respond to L-BCGF. Examination of Table 1 shows that L-BCGF-cultured cells from 28 of 37 patients underwent a significant increase in ³H-TdR incorporation compared to control cells cultured without L-BCGF. Cell sorting experiments confirmed that, in most cases, the CALLA/CD10 positive leukemic cells were responding

Table 3. Comparison of the B Cell Precursor ALL Response to Partially and Highly Purified L-BCGF

Culture Conditions		Response*	Stimulation Index†
No L-BCGF		3,872 ± 69‡	—
Highly purified L-BCGF	0.1%	8,713 ± 1,434	2
	1.0%	29,277 ± 6,065	8
Partially purified L-BCGF	5.0%	14,400 ± 67	4
	10.0%	35,046 ± 2,102	9

*Leukemic cells from patient No. 36 (Table 1) had been maintained in partially purified (Cytokine Technology) L-BCGF for 20 days, followed by L-BCGF-free medium for 25 days. The cells were then cultured with various concentrations of partially or highly purified L-BCGF for 96 hours and were pulsed with ³H-TdR for the final eight hours.

†See Table 1.

‡See Table 1.

directly to L-BCGF (Table 2), although exceptions were noted (patient No. 8). The L-BCGF response of CALLA/CD10 positive cells from patient to patient showed broad variation (Table 2), and explanations for this difference are discussed below. A critical experiment in this study was the direct comparison of the B cell precursor ALL response to partially purified (Cytokine Technology) and highly purified L-BCGF.²⁹ Data in Table 3 show that the proliferative response of B cell precursor ALL to the two L-BCGF sources was essentially the same. A second critical experiment was the demonstration that L-BCGF promoted colony formation of fresh B cell precursor ALL in vitro (Fig 4A). Increases in absolute cell numbers were also demonstrated in suspension cultures (Fig 2), although the responses were variable. Some leukemic specimens (eg, Figs 2C, 2D) showed an increase in ³H-TdR incorporation with no increase in absolute viable cell number. This suggests that the dividing cells may only be compensating for the cells dying in culture, and L-BCGF is not able to numerically expand these cells in vitro.

Several variables could be invoked to explain the patient-to-patient variability in response to L-BCGF, including: (1) differences in L-BCGF receptor expression/affinity that may reflect distinct stages of development at which a given leukemia is arrested, (2) dependency on external growth factors other than (or in addition to) L-BCGF, (3) dependency on accessory cells such as monocytes or T cells, and (4) dependency on an autocrine growth mechanism. Accessory cell dependency seems unlikely, since highly purified (>99%) CALLA/CD10 positive leukemic cells underwent a rigorous response to L-BCGF (Table 2). Dependency on other growth factors is a plausible explanation. One obvious candidate is IL 2, since this lymphokine has been shown by numerous laboratories to induce normal B cells to proliferate and/or differentiate.¹²⁻²³ Touw et al³⁴ showed that IL 2 enhanced B cell precursor ALL colony formation in the presence of leukocyte feeders. In contrast, we could find no role for IL 2 in the proliferation of B cell precursor ALL. Furthermore we studied 12 L-BCGF responders in Table 1 for their response to L-BCGF and 10 to 100 units/mL of IL 2 but found no evidence for a synergistic effect (data not shown). The discordance between our IL 2 results and those of Touw et al³⁴ might be attributable to the assay systems under study, ie, colony formation v ³H-TdR incorporation.

We feel that L-BCGF receptor expression may well explain the patient-to-patient variability observed in Tables 1 and 2. This variability could manifest itself at the quantitative level of L-BCGF receptor expression or at the level of signal transduction subsequent to binding of L-BCGF to its receptor. A resolution of these various possibilities awaits identification and characterization of the L-BCGF receptor.

In conclusion we have shown that the majority of B cell precursor ALL undergo a direct proliferative response to L-BCGF. We found no general role for IL 2 in B cell precursor ALL proliferation. Thus we believe L-BCGF may

be the predominant but not necessarily sole growth stimulus. The possibility that perturbation of L-BCGF/L-BCGF receptor interaction might disrupt growth of B cell precursor ALL should now be considered.

ACKNOWLEDGMENT

The authors thank Dr John Kersey for reading the manuscript; Dr Kazimiera Gajl-Peczalska and the Cell Marker Laboratory for provision of the leukemic specimens; Janet Anderson and Rose Sandler for technical assistance; and Katie Quinn for preparing the manuscript.

Epitope Mapping of Functional Domains of Human Factor Va With Human and Murine Monoclonal Antibodies. Evidence for the Interaction of Heavy Chain With Factor Xa and Calcium

By Anjanayaki E. Annamalai, A. Koneti Rao, Hui Chong Chiu, Danny Wang, Asim K. Dutta-Roy, Peter N. Walsh, and Robert W. Colman

We have purified a unique neutralizing IgG₁, κ monoclonal antibody (MAb) against factor V (F-V) from a patient's plasma. This MAb (H2) demonstrated specificity for human F-V heavy chain (D), mol wt 105,000. Using an enzyme-linked immunosorbent assay (ELISA) we assessed the competitive binding to F-Va of H2, H1 (human MAb directed to light chain, F1F2), and two murine MAbs, B38 (to F1F2) and B10 (to activation peptide C1). All four antibodies are of high affinity with K_D varying from 0.17 to 1.17×10^{-10} mol/L. They recognized distinct epitopes in F-V. F-Xa competed in a concentration-dependent fashion for binding of H1, H2, and B38 but not B10 to F-V/Va in the absence of phospholipids or platelets. Thus both F1F2 and

D polypeptides of F-Va but not C1 interacted with F-Xa. All MAbs bound to F-V/Va in the absence of Ca^{++} . However, free Ca^{++} (0.1 to 4.0 mmol/L) increased the amount of H1 and H2 bound to factor V/Va, 1.65-fold and 3.65-fold, respectively but had little effect on the binding of either murine MAbs. Prothrombin (20 $\mu\text{g/mL}$ to 400 $\mu\text{g/mL}$) in the absence of phospholipid did not inhibit the binding of MAbs. These studies provide evidence for the first time for a direct interaction between human F-Va heavy chain and F-Xa and Ca^{++} and for the direct binding of F-Xa to F-Va in the absence of phospholipids or platelets and enhance our understanding of functional F-V domains.

METHODS

Materials. Goat antirabbit IgG conjugated with alkaline phosphatase, paranitrophenyl phosphate, alkaline phosphatase, type VII-T, and protein A-Sepharose CL-4B were obtained from Sigma Chemical Co, St Louis. Human immunoglobulin subtyping kits were purchased from Miles Laboratories, Elkhart, IN. Reacti-Gel (6X) was purchased from Pierce Chemical Co, Dekalb, IL. Kodak X-Omat AR x-ray film was obtained from Eastman, Kodak Co, Rochester, NY; (p-Amidinophenyl)methanesulfonyl fluoride (p-APMSF) from Calbiochem, Behring Diagnostics, La Jolla, CA; and N-Benzoyl-L-isoleucyl-L-glutamyl-glycyl-arginine-p-nitroanilide hydrochloride (S-2222) from Kabi Vitrum AB, Helena Laboratories, Beaumont, TX. Ninety-six-well polystyrene Nunc-Immuno-plates were from Thomas Scientific Co, Swedesboro, NJ. Purified thrombin (3209 NIH U/mg) was a gift from Dr John Fenton, New York State Department of Health. All other chemicals were of reagent grade.

Human monoclonal antibody (H2) against human factor V. Blood was collected from the patient with acquired neutralizing antibody to factor V⁷ in 1:10 vol of 3.8% sodium citrate. The plasma was prepared by centrifuging blood for ten minutes at 2,000 g at room temperature and stored at -70°C . For purification of antibody the plasma was incubated at 56°C for 30 minutes to dissociate the antigen-antibody complexes.⁷ The IgG fraction was then precipitated with 45% saturated ammonium sulfate. The precipitate was dissolved in 0.02 mol/L Tris buffer, pH 7.2 containing 0.15 mol/L

HUMAN PLASMA factor V is a procofactor in the prothrombinase complex, which includes activated factor X, calcium and phospholipids, or platelets. When activated by thrombin, factor V (Va) accelerates the conversion of prothrombin to thrombin by several orders of magnitude. Mouse monoclonal antibodies (MAbs) against bovine¹ and human² factor V have been described. The formation of complexes composed of bovine factor V and MAbs has been demonstrated using light scattering and radioimmunoassay (RIA).¹ Two of the murine MAbs against bovine factor V have been shown to react respectively with the 94,000- and 74,000-dalton polypeptides that are noncovalently linked by Ca^{++} to form bovine factor Va.³ Foster et al² developed ten mouse MAbs against human factor V and demonstrated that one of them reacted with the light chain F1F2 (mol wt 71,000/74,000) of human factor Va. A naturally occurring human MAb antibody (H1) reported by Coots et al⁴ has been shown by Wilson et al⁵ to be specifically reactive against the light chain of human factor Va. We have recently characterized two murine MAbs against human factor V, B38, and B10 and demonstrated that they recognize epitopes on F1F2 and an activation peptide (mol wt 150,000) respectively in thrombin-cleaved factor V.⁶ To date no MAb has been reported specific to the heavy chain (D) of human factor Va, mol wt 105,000.

Recently we reported human MAbs circulating with human factor V as immune complexes in a patient.⁷ In this paper we describe the purification of a single class of immunoglobulin, IgG 1, with κ light chain containing factor V neutralizing antibody from the plasma of that patient and its characterization as specific for a site on the D polypeptide of factor Va. We then determined the relationship between the epitope of this antibody (H2) and other MAbs against human factor V developed (B38, B10) or purified (H1) in our laboratory. MAbs to specific epitopes should be useful probes to study the structure and function relationships of human factor V/Va. Therefore we studied the interaction of prothrombin and two components of prothrombinase complex (factor Xa and Ca^{++}) with these MAbs to characterize better the spatial arrangement of these components with respect to distinct sites in factor V/Va.

NaCl (TBS), dialyzed at 4°C against the same buffer with two changes, and filtered through a 0.22 µm filter. The clarified solution was then dialyzed overnight at 4°C against citrate-phosphate buffer, pH 7.0 (0.1 mol/L citric acid was added to 0.2 mol/L Na₂HPO₄ until the desired pH was obtained). Chromatography of this sample on Protein A-Sepharose column was performed according to the procedure of Duhamel et al.⁸ The heavy chain subclass and the light chain type of IgG eluted from the column were determined by enzyme-linked immunosorbent assay (ELISA) using rabbit antibodies to human immunoglobulin subtypes and alkaline phosphatase-conjugated goat antirabbit IgG.

Human monoclonal antibody (H1) against factor V. Human plasma-containing inhibitory activity against factor V was a kind gift of Dr Helen Glueck, Cincinnati, OH and was purified as described by Chiu et al.⁹ H1 is IgG4, λ subtype, neutralizes factor V activity and is directed to factor Va light chain (F1F2).

Preparation and characterization of murine monoclonal antihuman factor V (B38 and B10). The murine MABs were prepared in our laboratory as described earlier¹⁰ and have been extensively characterized.⁶ The immunoglobulin type of each is IgG1 κ. B38 neutralizes factor V activity and is directed to the light chain (F1F2). B10 does not neutralize factor V activity but recognizes an epitope on the activation peptide (C1).

Purification of human plasma factor V. Factor V was purified by an immunoaffinity procedure⁹ adapted for a murine monoclonal antifactor V (B38) instead of a human MAB. The immunoabsorbent was prepared identically,⁹ but nonspecifically bound proteins were removed by washing with 0.02 mol/L Tris buffer, pH 7.2 containing 0.37 mol/L NaCl followed by a wash with the same buffer containing 5% glycerol. The specifically bound factor V was eluted with the Tris buffer containing 0.15 mol/L NaCl, 25% glycerol and 50% ethylene glycol. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of the purified factor V showed a single band corresponding to the mol wt of 330,000. The specific activity ranged from 70 to 100 U/mg and increased to 17- to 20-fold upon activation with thrombin.

Radiolabeling of human factor V. Purified factor V was labeled with ¹²⁵I by the iodogen method as modified by Tuszyński et al.¹¹ The radiolabeled factor V had a specific activity of 4.67×10^6 cpm/µg.

Thrombin activation of ¹²⁵I human factor V. Radiolabeled factor V (1 to 2 U/mL) was activated with thrombin (0.05 to 0.1 U/mL) as described by Annamalai et al.¹⁰

Epitope specificity of human monoclonal antihuman factor V (H2). Purified human monoclonal IgG was coupled to Reacti-Gel 6X. To remove acetone the suspension of Reacti-Gel (500 µL) was washed on a coarse-fritted glass-filter funnel with gentle suction and several bed volumes of ice cold water. The moist cake was transferred to 400 µL of 0.1 mol/L borate buffer, pH 8.0 in an Eppendorf tube containing 0.25 mg/mL human monoclonal IgG or normal human IgG (control). The mixtures were rotated end over end overnight at 4°C. At the end of incubation the gel-ligand mixtures were centrifuged at 12,000 g in a microcentrifuge for four minutes. The precipitates were washed with ice-cold 0.5 mol/L Tris buffer pH 8.0 two times and left overnight at 4°C in the same buffer with gentle mixing. The suspensions were centrifuged and resuspended in 0.075 mol/L Tris buffer pH 7.2 containing 0.075 mol/L NaCl, 20 mmol/L Ca⁺⁺, or 20 mmol/L EDTA and 0.1% bovine serum albumin (BSA). Radiolabeled factor Va, 0.15 µg (0.7×10^6 cpm) was added to these tubes and incubated overnight with mixing. Then the gel-ligand mixtures were transferred to disposable plastic columns with filter discs and washed successively with 10 mL each of the following buffers to remove all the unadsorbed and nonspecifically adsorbed materials from the immunoabsorbents: Buffer 1, 0.02 mol/L Tris pH 7.2, 0.15 mol/L NaCl, 0.1% BSA, 0.1% Tween-20, and 20 mmol/L Ca⁺⁺ or EDTA; Buffer 2, 0.02 mol/L Tris, pH 7.2, 0.5 mol/L NaCl, 0.1% BSA, and 20 mmol/L Ca⁺⁺ or EDTA;

Buffer 3, 0.02 mol/L Tris, pH 7.2, 0.15 mol/L NaCl, and 20 mmol/L Ca⁺⁺ or EDTA. The immunoabsorbents containing specifically bound factor Va polypeptide were transferred to Eppendorf tubes and centrifuged for four minutes. The pellets were suspended in 10% sodium dodecyl sulfate (SDS), boiled for ten minutes to dissociate the antigen, and centrifuged. The supernatants containing radiolabeled factor Va fragment then were electrophoresed.

SDS slab-PAGE and autoradiography. Electrophoresis was performed using 3% to 15% gradient polyacrylamide gel in a Tris buffer system according to the method of Laemmli.¹² Purified factor V, Va, fibrinogen, and mol wt standards consisting of myosin (200,000), phosphorylase B (97,400), BSA (68,000), Ovalbumin (43,000), α-chymotrypsinogen (25,700), β-lactoglobulin (18,400), and cytochrome C (12,300) were applied along with the samples. The gels were fixed and stained with Coomassie brilliant blue R for protein. After destaining the gels were dried and subjected to autoradiography with Kodak X-Omat AR x-ray film.

Conjugation of purified MABs to alkaline phosphatase. MABs were dialyzed against 0.02 mol/L Na phosphate containing 0.15 mol/L NaCl, pH 7.2 phosphate-buffered saline (PBS) overnight at 4°C. Alkaline phosphatase (921 units) and 25% glutaraldehyde (final concentration 0.2% vol/vol) were added to 0.2 mg of anti-V IgG in a total volume of 1.5 mL. The mixture was incubated for two hours at room temperature and then dialyzed against PBS overnight with two changes. The enzyme-antibody conjugate was further dialyzed against 0.05 mol/L Tris buffer, pH 8.0 containing 1 mmol/L MgCl₂ at 4°C with two changes. 1% BSA and 0.02% Na₂S₂O₃ were added to the conjugate and stored at 4°C.

Binding specificity of alkaline-phosphatase conjugated and unconjugated MABs to factor V/Va. Since epitope mapping was carried out using enzyme-conjugated and unconjugated antibodies, it was first necessary to determine whether conjugation affected the ability of the MABs to bind to factor V/Va. A competitive ELISA (cELISA) was employed to accomplish this goal and was performed as previously described⁹ using microtiter plates coated with purified factor V/Va. The plates were incubated overnight at 4°C with each of the conjugated and unconjugated antibodies, predetermined to give 70% saturation of the antigenic sites along with increasing concentrations of purified factor V/Va (0.095 nmol/L to 3.04 nmol/L). After extensive washing the amount of bound enzyme-antibody conjugate was detected by incubating with p-nitrophenyl phosphate. Controls without antigen but containing the anti-V antibody-enzyme conjugate and substrate or without the antibody-enzyme conjugate but containing the antigen and substrate were included to correct for the nonspecific binding. Each experiment was done in triplicate.

Dissociation constants (K_D) of purified MABs for their antigenic determinants. The dissociation constants of the purified murine and human MABs to human factor V/Va were determined by the method of Friguet et al.¹³ The absorbance at 405 nm resulting from the enzymatic activity of the immunoconjugate bound to the adsorbed factor V/Va v various concentrations of each of the purified MAB in ELISA was found to be linear. A concentration of each antibody that saturated 60% to 70% of the antigenic determinants of the adsorbed factor V/Va was then incubated with various concentrations of purified factor V/Va (0.57 nmol/L to 18.4 nmol/L) in equal volume overnight until equilibrium was reached. Free antibody concentration at equilibrium for each incubation mixture was determined by ELISA under the same conditions as was done initially for choosing the antibody concentration. Absorbance (A_o) measured in ELISA for the incubation mixture containing only the antibody without added antigen would be related to the total antibody concentration, (Ab)_t. For the total antibody concentration, (Ab)_t incubated with a given antigen concentration, at equilibrium the absorbance (A) measured in ELISA would be related to the free antibody concentration, (Ab)_f. The method is applicable even in the

case of unpurified antibodies. From a plot of $A_{500}/A_{500} - A_{500} \nu 1/(Ag)_t$, the K_D can be calculated from the slope.¹⁴

Epitope mapping of the four MAbs against factor V. The epitope map of factor V/Va was determined by using the MAbs (H1, H2, B38, and B10) in a cELISA. Purified factor V, 40 ng in 200 μ L of TBS was coated onto the surface of 96-well polystyrene microtiter plates by incubating overnight at 4°C. The plates subsequently were washed and the remaining sites blocked as described before. The concentrations of MAb-enzyme conjugates to be used were selected based on separate experiments (data not shown). To saturate, all the antigenic sites were added in the absence or presence of 4 to 6X molar excess of unconjugated anti-V IgG. The mixture was incubated overnight and washed as before. Appropriate controls were included as described before to correct for the nonspecific binding. The absorbance resulting from the enzymatic activity of each immunoconjugate bound to the antigen in the absence of any unconjugated antibody was taken to represent the total binding. The absorbance in the presence of other unconjugated MAb was represented relative to the total binding.

Purified human factor Xa and human prothrombin. Factor Xa (125 U/mg) and prothrombin (12 U/mg) were prepared as described by Walsh et al.¹⁵

Effect of factor Xa on MAb binding to factor V/Va. The competition of factor Xa for the binding of the various monoclonal anti-V IgG to the adsorbed factor V/Va in the solid phase system was determined by using ELISA. The polystyrene 96-well plates were coated with factor V/Va as before and incubated with increasing concentrations of factor Xa in 100 μ L of TBS. After two-hour incubation at 4°C, various MAb-enzyme conjugates, predetermined to give the maximal binding to adsorbed factor V/Va, were added in equal volume as factor Xa. The plates were reincubated overnight at 4°C, washed, and the bound anti-V IgG-enzyme conjugates measured as before.

Effect of factor Xa inactivated by (p-Amidinophenyl) methane-sulfonyl fluoride (p-APMSF) on MAb binding to factor V/Va. Factor Xa (2.27 μ mol/L) was inactivated with tenfold molar excess of p-APMSF at room temperature for 30 minutes as described by Laura et al.¹⁶ Factor Xa, treated in the same manner but without the reagent, was used as a control. The enzymatic activity of F-Xa after incubation with p-APMSF measured with the substrate S-2222 was less than 10% that of the control. The effect of inactivated F-Xa on the binding of MAbs was carried out as before.

Effect of prothrombin on MAb binding to factor V/Va. The experiments were carried out as described for the studies on the effect of factor Xa but in the presence of various concentrations of prothrombin.

Effect of Ca^{++} on the monoclonal anti-V IgG binding to factor V/Va. The competition of Ca^{++} for the binding of MAbs was done using ELISA as for factor Xa and prothrombin. Factor V/Va was adsorbed to 96-well microplates and incubated with monoclonal anti-V conjugates in 0.05 mol/L Tris buffer, pH 7.5, containing 4 mmol/L EDTA and 10 mmol/L $MgCl_2$ and increasing concentrations of Ca^{++} . Magnesium chloride was added to the buffer to prevent a pH change owing to the liberation of H^+ ions from EDTA as calcium was added. Using the known equilibrium constants for each of the ionic species in this buffer at this pH, the concentration of the free calcium was calculated by a computer program as described by Perrin and Sayce.¹⁷ Incubation, washing, and detection of the bound antibody-enzyme conjugates were carried out as before.

RESULTS

Human MAbs against human factor V. Previous characterization of MAbs against factor V in a patient revealed that the patient's plasma neutralized factor V coagulant activity in normal plasma to 95% at a ratio of 16:1 (vol/vol)

and that these antibodies were of the immunoglobulin subclasses IgG1 and IgG2 with κ light chain. No factor V antibody activity was associated with subclasses IgG3 and IgG4.⁷ The IgG fraction in the patient's plasma has now been partially purified by precipitation with 45% of saturated ammonium sulfate and applied to a protein A-Sepharose column. Human IgG1 and IgG2 both bound strongly to protein A and were resolved by elution with a pH gradient.⁸ Two peaks of A_{280} , one small peak at about pH 5.2 and another more prominent peak around pH 4.2, were eluted. The latter peak was pooled and characterized as containing IgG1 and κ light chain and used in the studies reported here. SDS-PAGE of the purified anti-V IgG under nonreduced condition showed a single band corresponding to a mol wt of 150,000 daltons and under reduced condition two bands of 50,000 and 25,000 daltons. The IgG1 fraction (0.3 mg/mL) neutralized the factor V coagulant activity in normal plasma almost completely at a ratio of 4:1 (vol/vol).

Epitope Specificity of human MAbs (H2). To determine the antigenic specificity of the antibody,¹²⁵I factor V was cleaved with thrombin and reacted with either antibody (H2) or normal human IgG (control), coupled to Reacti-gel 6X, in the presence of either 20 mmol/L Ca^{++} or EDTA as described in "Methods." The specifically bound component of factor Va was identified as the heavy chain (D polypeptide, mol wt 150,000) by comparison with known factor Va after electrophoresis on a SDS polyacrylamide gel followed by autoradiography (Fig 1). The presence of 20 mmol/L EDTA completely eliminated the binding of factor Va to this immobilized human MAb. Moreover no detectable light chain (F1F2 polypeptide) was adsorbed along with the D polypeptide in the presence of 20 mmol/L Ca^{++} .

Binding specificity of alkaline phosphatase-conjugated and unconjugated MAbs. The activity of the enzyme-conjugate was inversely proportional to the added factor V/Va in a competitive assay. Both conjugated and unconjugated antibody (B10, H1, H2, and B38) gave dose responses that could be described by the same line (data not shown). Thus all the four MAbs, in their abilities to bind to factor V/Va, were unaffected by conjugation.

Dissociation constants (K_D) of purified MAbs for their antigenic determinants. The dissociation constants of antigen-antibody equilibrium in solution was determined using ELISA. When plotted according to the Klotz equation,¹⁴ an excellent fit to a straight line with a correlation coefficient of 0.974 to 0.998 and intercept to ordinate close to 1 were obtained for all the four MAbs. From linear regressions the K_D values obtained were as follows: 1.15×10^{-10} mol/L for B10, 0.30×10^{-10} mol/L for B38, 0.17×10^{-10} mol/L for H1, and 0.78×10^{-10} mol/L for H2.

Epitope mapping of the four MAbs against human factor V. The epitope specifications of the MAbs against human factor V developed and/or purified in our laboratory were examined by reciprocal competitive inhibition of binding of antibody to antigen. Alkaline phosphatase-conjugated MAbs were employed as probes in direct ELISA in the absence or presence of other unconjugated MAbs ("Methods"). As expected, the binding of B10 enzyme-conjugate was inhibited almost completely (100%) in the presence of unconjugated B10 monoclonal IgG (Fig 2). The inhibition was nearly

Fig 1. Epitope specificity of the human monoclonal antihuman factor V (H2): autoradiogram of SDS polyacrylamide gel. The affinity-purified monoclonal IgG or normal human IgG, 0.25 mg/mL, was coupled to Reacti-gel 6X in 0.1 mol/L borate buffer pH 8.0. After coupling, the gel-IgG conjugates were centrifuged and resuspended in 0.075 mol/L Tris buffer pH 7.2 containing 0.075 mol/L NaCl, 0.1% BSA, and 20 mmol/L Ca^{++} or 20 mmol/L EDTA. ^{125}I -labeled factor Va, 0.15 μg (0.7×10^6 cpm) was added to each tube and incubated overnight at 4°C with mixing. The gel-ligand mixtures were washed to remove nonspecifically adsorbed proteins. Specifically bound factor Va fragment was dissociated from the complex by boiling in 10% SDS for 10 minutes, electrophoresed on 3% to 15% gradient SDS polyacrylamide gel, and then dried gel applied to autoradiography. Lane 1, factor V; Lane 2, factor Va; Lanes 3 and 4, antibody H2 eluates obtained in the presence of EDTA and Ca^{++} ; Lanes 5 and 6, normal human IgG eluates obtained in the presence of EDTA and Ca^{++} .

80% in the presence of H1, but the presence of B38 or H2 did not interfere with the binding.

The binding of B38 enzyme-conjugate to factor V/Va was totally abolished in the presence of B38. A small degree of inhibition to an extent of 30% and 15% was observed in the presence of B10 and H1 respectively. H2 did not interfere with the binding of B38 enzyme-conjugate to factor V/Va.

With alkaline phosphatase-conjugated H2, the inhibition was total in the presence of unconjugated H2 and strikingly about 72% in the presence of B10. The presence of B38 or H1 did not have any effect on the binding of H2.

The binding of H1 enzyme-conjugate to adsorbed factor V was totally eliminated in the presence of H1 antibody. In the presence of B38, B10, and H2, the binding of H1 anti-V IgG-conjugate was inhibited to about 50%.

Effect of factor Xa on the binding of monoclonal antihuman factor V IgG to factor V/Va. We measured the binding of a predetermined saturating concentration of the

Fig 2. Epitope mapping of the MABs against factor V. Affinity-purified antibodies were conjugated to alkaline phosphatase. Purified factor V/Va, 40 ng in 200 μL of 0.02 mol/L Tris buffer, pH 7.2, containing 0.15 mol/L NaCl was coated onto the surface of 96-well microplates by incubating overnight at 4°C. After incubation the plates were washed with the same buffer containing 1% BSA and reincubated with BSA containing buffer overnight. Monoclonal anti-V IgG-enzyme conjugate in the absence or presence of 4 to 6X excess amounts of various unconjugated MABs were incubated overnight. After washing to remove unadsorbed proteins, the bound antibody-enzyme conjugate was detected by incubating with the substrate of the enzyme. ■, MAB-enzyme conjugate alone; ▨, MAB-enzyme conjugate and unconjugated B38; ▤, MAB-enzyme conjugate and unconjugated B10; ▩, MAB-enzyme conjugate and unconjugated H2; ▪, MAB-enzyme conjugate and unconjugated H1.

various monoclonal anti-V IgG to 40 ng of adsorbed factor Va in the presence of varying amounts of factor Xa ranging from 0.1 $\mu\text{g}/\text{mL}$ to 4.0 $\mu\text{g}/\text{mL}$. As shown in Fig 3, there was a concentration-dependent competition of factor Xa for the binding of the monoclonal anti-V IgG B38, H1, and H2 to factor V/Va. The binding of these antibodies was decreased 80% to 90% in the presence of 4 $\mu\text{g}/\text{mL}$ of factor Xa. In contrast, the binding of B10, an antibody that is neither neutralizing nor directed against factor Va, was reduced only about 20%.

Effect of factor Xa inactivated by (p-Amidinophenyl) methanesulfonyl fluoride (p-APMSF) on MAB binding to factor V/Va. Tracy et al¹⁸ demonstrated that factor Xa proteolytically modified bovine factor Va. Thus we tested whether the decrease in the binding of anti-V IgG B38 to factor V/Va in the presence of added F-Xa was due to proteolysis of factor V/Va by F-Xa. We found that F-Xa incubated with p-APMSF and containing less than 10% of its original activity reduced the binding of B38 virtually identical to that of active F-Xa. Thus at a F-Xa concentration of 0.36 $\mu\text{g}/\text{mL}$, the relative absorbance (A_{405} ; with control without factor Xa defined as 1.0) for active F-Xa was 0.685 of the absorbance in the absence of F-Xa, while for inactivated F-Xa, 0.682. Similarly, at 1.43 $\mu\text{g}/\text{mL}$, the relative absorbance was 0.164 for active F-Xa and 0.160 for inactivated F-Xa. To test whether F-Xa inactivated by p-APMSF could still cleave factor Va, labeled factor Va (0.4×10^{-9} mol/L) was incubated with inactivated F-Xa (2.0×10^{-8} mol/L) overnight at 4°C. The sample was electrophoresed on 3.5% to 15% gradient SDS polyacrylamide gels and subjected to autoradiogram along with a control sample without F-Xa. The autoradiogram of factor Va incubated with inactive F-Xa was identical (data not shown) to that of control (Fig 1). No cleavage of any of the components of

Fig 3. Effect of factor Xa on monoclonal anti-V binding to adsorbed factor V/Va. Microtiter plates were coated with factor V/Va and incubated with antibody-enzyme conjugate along with increasing concentrations of factor Xa (20 ng/200 μ L to 800 ng/200 μ L) overnight. After incubation the plates were washed extensively and the bound antibody-enzyme conjugate was detected by incubating with p-nitrophenyl phosphate 1 mg/mL in 0.05 mol/L sodium carbonate pH 9.8 containing 1 mmol/L $MgCl_2$. $\square$ — $\square$, B10; $\times$ — $\times$, B38; $\bullet$ — $\bullet$, H1; $\circ$ — $\circ$, H2.

factor Va was noted. These results suggested that the effect of F-Xa on the binding of MABs to factor V/Va was not due to proteolytic cleavage of factor V/Va by F-Xa.

Effect of prothrombin on the binding of Antihuman factor V IgG to factor V/Va. The direct binding of thrombin-treated factor V to prothrombin has been demonstrated¹⁹ using partially purified bovine factor V and bovine prothrombin-sepharose affinity column. Therefore we examined the binding of the various MABs to immobilized factor V/Va in the presence of increasing concentrations of human prothrombin ranging from 20 μ g/mL to 375 μ g/mL. Prothrombin at these concentrations did not compete with the binding of any of the MABs to adsorbed factor V/Va, and the binding ranged from 89.4% to 106.3% of the value without added prothrombin.

Effect of Ca^{++} on the binding of Antihuman factor V IgG

Fig 4. Effect of Ca^{++} on monoclonal anti-V binding to factor V. Factor V/Va was adsorbed to 96-well plates, and various enzyme-conjugated MABs were incubated with increasing amounts of Ca^{++} in 0.05 mol/L Tris buffer, pH 7.5, containing 4 mmol/L EDTA and 10 mmol/L $MgCl_2$. Incubation, washing, and detection of the bound antibody were determined as described in the legend for Fig 3. Free Ca^{++} present in the reaction mixture was calculated by using a computer program described in "Methods." In the absence of added Ca^{++} , the reaction mixture does not contain any free Ca^{++} . $\square$ — $\square$, B10; $\times$ — $\times$, B38; $\bullet$ — $\bullet$, H1; $\circ$ — $\circ$, H2.

to factor V/Va. Metal ions such as Ca^{++} , Mn^{++} , Co^{++} , and Cd^{++} have been shown to maintain bovine factor Va activity.²⁰ An association and/or direct binding of calcium to factor V/Va has also been observed.^{21,23} We examined the effect of Ca^{++} on the binding of the different MABs that have distinct epitope specificities to factor V/Va as described in "Methods." As shown in Fig 4, all four MABs had the ability to bind to adsorbed factor V/Va in the absence of added Ca^{++} . However, in the presence of varying concentrations of Ca^{++} in the incubation mixture, their ability to bind differed strikingly. An increase in the binding of the two human monoclonal antibodies, H1 and H2, was noted as the physiologic concentration of Ca^{++} (1.3 mmol/L) was approached. At 4 mmol/L, the absorbance related to the binding of H1 increased 1.65-fold, while that of H2 increased 3.65-fold. In contrast, there was little or no effect on the binding of the two murine MABs.

DISCUSSION

Previously we described two MABs to factor V in a patient that were typed as a mixture of IgG₁ of IgG₂ with κ light chains. We have now purified an IgG₁ fraction containing the MAB (H2) from the plasma of this patient and determined that it is directed against the heavy chain of factor Va (D polypeptide). This fraction contains an antibody that contains a single class of heavy chain and light chain, a single class of binding sites with a K_D of 0.78×10^{-10} mol/L, and reacts with the single chain of factor V. These data strongly suggest that it is a "monoclonal" antibody, although absolute proof for a naturally occurring human antibody is difficult to obtain. This report is the first description of a MAB to human factor V/Va, which recognizes an antigenic site on the D chain of human factor Va.

The requirement of two polypeptides bridged by Ca^{++} for the integrity of factor Va activity is well established.^{21,24} Using anti-bovine factor V MABs, Tracy and Mann²⁵ and Tucker et al²⁶ have described the functional significance of light chain of factor Va in some detail and found that it is involved in the interaction with factor Xa and platelets. The phospholipid or platelet-bound factor Va is inactivated by activated protein C as a result of the cleavage of D polypeptide, and factor Xa protects against this inactivation,^{18,27,28} suggesting the possibility that factor Xa also interacts with the heavy chain of factor Va. However, the exact contribution of D polypeptide of human factor Va to the function of prothrombinase complex is not established. By using this human MAB (H2) as probe, we have defined more specifically the role of D polypeptide of human factor Va.

In determining the epitope specificity of the human MAB (H2) we have made two observations that are unexpectedly different from results with antibodies to the D chain of bovine factor V and hence interesting. First, in the presence of 20 mmol/L EDTA the labeled factor Va was not immunoprecipitated with the antibody H2, in contrast to its behavior in the presence of 20 mmol/L Ca^{++} . It may be that the binding of this antibody to factor V/Va is weak in the presence of EDTA and the antigen lost during extensive washing with the buffer containing detergent and high salt.

Second, only the heavy chain (D) of factor Va binds to H2 in the presence of Ca^{++} , and the light chain (F1F2) is not coadsorbed. This observation indicates that the binding of MAb may disrupt the Ca^{++} -mediated association of the two components of factor Va. This effect could arise through steric hinderance, conformational changes, or binding at or near the Ca^{++} binding site in the D polypeptide. These results contrast with the observations of Foster et al with the bovine factor V.³ The two monoclonal bovine anti-factor V antibodies, $\alpha_1\text{D}$, $\alpha_2\text{D}$ (D polypeptide-specific) and $\alpha_2\text{E}$ (the light chain or E polypeptide-specific) immunoprecipitate both the heavy and light chain of bovine factor Va in the presence of Ca^{++} . With bovine factor V, therefore, the binding of antibody to the D or E polypeptide does not perturb the integrity of the two-subunit bovine factor Va molecule in the presence of Ca^{++} . Wilson et al⁵ has determined that the human MAb (H1), reported by Coots et al,⁴ is light-chain specific. They find that the heavy chain is immunoprecipitated to a much lesser extent compared to the light chain of labeled factor Va with the antibody in the presence of Ca^{++} . This finding is similar to what we observed with the human MAb (H2). We have also found this preferential behavior with the murine monoclonal antihuman factor V, B38 (Doshi and Colman, unpublished observation). Thus this result reflects a weaker Ca^{++} dependent association between the two chains of factor Va in human compared to that in bovine plasma. These results are also consistent with the observations that bovine factor Va is more stable than the human factor Va, which in part may be due to tighter calcium binding.

The dissociation constants obtained for the four antibodies varied from 0.17 to 1.15×10^{-10} mol/L, indicating that the Mabs are of high affinity. The two human antibodies (H1 and H2) each may represent only a portion of the purified IgG preparation, which also probably contains multiple antibodies to different antigens. The method employed in the studies here allows the measurement of true K_D in solution of antibody-antigen complexes by ELISA, since the derived equation is independent of the absolute antibody concentration and depends on the relative amount of free antibody and the total antigen concentration. By separating the IgG1 from IgG2 in H2, we have avoided the only difficulty if these two antibodies to factor V should have overlapping specificity. Since IgG4 elutes in small amounts in both the IgG1 and IgG2 fraction, the possibility that IgG4 is the responsible species must be considered. However, Chiu et al⁷ have shown previously that only IgG1 and IgG2 subclasses contain antibodies that bind to factor V in an ELISA assay.

The data obtained from the reciprocal competitive inhibition of the binding of antibodies to the antigen provide insight into the spatial relationship of the polypeptide domains in the human factor V/Va molecule. The electron microscopic structure of human factor V/Va of Dahlback et al²⁹ provides a framework for interpretation (Fig 5), although the identification of each polypeptide is not certain. In all cases the unconjugated antibody completely competes with the same conjugated antibody, thereby further validating the system. The uninhibited binding of antibody-conjugate to the antigen in the presence of excess amounts of

other unconjugated antibodies is taken to indicate that the two epitopes are independent. The scheme is conceptually useful but does not imply any firm conclusion about actual molecular distances.

Partial inhibition observed between some antibodies could be explained by weak or strong steric hinderance between the conjugated and inhibitor antibodies, inducing an apparent decrease in the binding of the antibody-enzyme conjugate to the antigen. Human MAb H1 and mouse MAb B38 are both specific to the F1F2 polypeptide of human factor Va, and B10 mouse MAb is specific to the activation peptide. The binding of B10 conjugate, as shown in Fig 2, is reduced by 80% in the presence of H1 but remains unaffected in the presence of B38. The data indicate first that the epitopes of B38 and H1 in the light chain of factor Va are distinct and second that the antigenic determinant of H1 may be in close proximity to the epitope of B10 antibody in the activation peptide.

Binding, kinetic, and immunochemical evidence all support a close interaction between factor Va and factor Xa.³⁰ Our results provide evidence that factor Xa can interact with factor Va in the absence of platelets or phospholipids. The failure of factor Xa to inhibit the binding of B10 suggests that factor Xa interacts with factor Va. Tucker et al²⁶ have found that the interaction of bovine factor Va and factor Xa in the presence of phospholipids is inhibited by an antibovine factor V MAb directed against the light chain. Tracy and Mann²⁵ have suggested that the light chain of bovine factor Va bound to platelets also serves as the binding site for factor Xa. Since the MAb B38 and H1 used in this study are both directed against the light chain of human factor Va,^{5,6} total inhibition of the binding of these two antibodies to factor Va by factor Xa is consistent with the earlier findings.

Previous studies present kinetic evidence for the interaction of polypeptide D of factor Va and factor Xa.^{18,27,28} Factor Va is inactivated by activated protein C by cleavage of polypeptide D, and factor Xa protects factor Va from this inactivation. Our observation in this paper is that the binding of H2 MAb, which is specific for the D polypeptide of factor Va (Fig 1), is inhibited competitively in the presence of increasing concentrations of factor Xa, which demonstrates existence of such an interaction between D polypeptide of factor Va and factor Xa. This finding is consistent with the previous observation that cleavage of the D polypeptide of bovine factor Va by protein C destroys its ability to bind to immobilized inactivated factor Xa.³¹ The possibility that our results are due to factor Xa cleavage of factor Va is ruled out by the similar behavior of inactive factor Xa.

Esmon et al¹⁹ have demonstrated the direct binding of bovine factor Va to prothrombin. More recently, Guinto and Esmon³¹ have demonstrated that the bovine factor Va heavy chain binds to prothrombin in a specific and Ca^{++} independent fashion. However, we find that prothrombin, even at concentrations higher than that of plasma, 375 $\mu\text{g}/\text{mL}$ does not inhibit the binding of any of the MAb tested. The prothrombin binding site in factor Va may be distinct from the epitopes recognized by these MAb. Alternatively, prothrombin may bind only to phospholipid or platelets or to a factor Va-lipid complex. Prothrombin may require factor Xa

Fig 5. Schematic diagram of factor V/Va functional epitopes. When the single chain factor V is activated to factor Va by thrombin, a number of polypeptides are formed. They are D (mol wt 105,000); F₁F₂ (mol wt 71,000 to 74,000); C₁ (mol wt 150,000), and E (mol wt 71,000). Functional domains and topographic relationships are defined from the data obtained in competitive inhibition experiments using human factor V MAbs, which recognize distinct epitopes in factor V/Va molecule.

to promote binding or may not bind to factor V/Va immobilized on plastic. Rosing et al³² have shown that phosphatidylserine exposed at the outer surface of stimulated platelets by collagen and thrombin promotes prothrombin and factor X activation. However, these kinetic studies do not distinguish between the above alternatives.

The effect of Ca⁺⁺ on the binding of these MAbs supports the results from competitive ELISA that the murine MAb B38 and human MAb H1 recognize distinct epitopes in the F₁F₂ polypeptide of factor Va. The binding of both human MAb (H1 and H2) to the antigen is increased by Ca⁺⁺, although the effect is more pronounced for H2 in contrast to the murine MAbs (B38 and B10). Hibbard and Mann have demonstrated three calcium-binding sites.²² It is likely that in

the presence of 4 mmol/L-free Ca⁺⁺, which is several fold excess of the reported values of the dissociation constants for the high and low affinity binding sites of Ca⁺⁺, all the sites are occupied. There may be an interaction between one or more of these Ca⁺⁺ sites and the epitopes recognized by the human MAbs. The data, however, do not distinguish between an increased number of antibody binding sites or an increased affinity of the antibody binding to factor V/Va.

ACKNOWLEDGMENT

A New Mutation in IVS-1 of the Human β Globin Gene Causing β Thalassemia Due to Abnormal Splicing

By George F. Atweh, Corinne Wong, Robin Reed, Stylianos E. Antonarakis, Ding-er Zhu, Prahbat K. Ghosh, Tom Maniatis, Bernard G. Forget, and Haig H. Kazazian, Jr

A G to T transversion at the fifth nucleotide of the first intervening sequence (IVS-1) of the β -globin gene has been identified in cloned β -thalassemia genes of two unrelated individuals, one of Mediterranean and the other of Anglo Saxon ancestry. In each patient the mutation was present in a different β globin gene framework, defined by intragenic restriction site polymorphisms, thereby suggesting the occurrence of independent mutations. The study of the RNA products of one of these cloned genes, after transfer

and transient expression in HeLa cells, showed partial inactivation of the normal donor splice site of IVS-1 and activation of two major and one minor cryptic splice sites. Only one of the two major cryptic sites was utilized in a cell-free splicing extract. The effects of this mutation on messenger RNA (mRNA) splicing are similar to that of another β thalassemia gene with a G to C transition at the same position.

© 1987 by Grune & Stratton, Inc.

β -THALASSEMIA is one of the commonest single gene disorders that has been recognized and studied by geneticists and hematologists for several decades.^{1,2} The interest in this disorder has recently intensified with the advent of recombinant DNA technology. Mediterranean and other populations have been investigated in great detail at the molecular level, and numerous lessons about gene structure and function in health and disease have been learned from these studies.^{3,4} The systematic approach for the study of this disease, advocated by Orkin et al.,⁴ has allowed the identification of a large number of mutant β -thalassemia genes. This approach is based on the strong correlation between specific mutations and certain chromosomal backgrounds, called haplotypes, defined by patterns of restriction fragment-length polymorphisms (RFLPs) in the β -globin gene cluster. In general, a given mutation is associated with a particular haplotype in a certain racial group. A survey of 164 Mediterranean β -thalassemic alleles has revealed a correlation of 86% between a given haplotype and a given thalassemic mutation.⁵ Using this approach we have characterized a new mutation from two unrelated individuals of different ethnic origins. This mutation changes the fifth nucleotide of the first intervening sequence (IVS-1 position 5) from G to T and alters the pattern of RNA processing.

MATERIALS AND METHODS

High mol-wt DNA was isolated from the spleen or leukocytes⁶ of affected individuals using the method of Blin and Stafford.⁷ Haplotype determination was performed by restriction endonuclease analysis⁸ using the same combination of restriction enzymes and DNA probes as that described by Orkin et al.⁴ The β -globin genes were cloned as 7.5 kb *Hind* III fragments, as described earlier.^{6,9} The Mediterranean β -thalassemia gene was subcloned as a 3.7 kb *Pst* I/*Bgl* II fragment in the expression vector π SVplac.¹⁰ DNA sequence analysis was performed by the dideoxy chain termination method of Sanger et al.¹¹

π SVplac recombinants containing a normal β -globin gene¹⁰ or a β -thalassemia gene were used to transfect HeLa cells at 25% confluency using the technique of DNA coprecipitation with calcium phosphate followed by glycerol shock, as described earlier.⁶ After 36 hours the cells were harvested, and cytoplasmic RNA was extracted using methods described by Favaloro et al.¹² The extracted RNA was used in S1 nuclease mapping experiments¹³ with either uniformly labeled single-stranded probes or 3' end-labeled double-stranded probes (see "Results" for description of specific probes). After S1 nuclease digestion, the protected DNA fragments were fractionated by electrophoresis in 5% or 8% polyacrylamide gels in

the presence of 7 mol/L urea. The products of RNA processing were also evaluated by primer extension studies.¹⁴ The RNA isolated from transfected HeLa cells was annealed to a 30-base synthetic oligonucleotide primer complementary to the RNA strand of exon 2, and cDNA copies of the RNA were synthesized using viral reverse transcriptase, as described.¹⁴ The products were analyzed by electrophoresis in an 8% urea-polyacrylamide gel using appropriate size markers. Cell-free splicing of truncated precursor β globin mRNA molecules, synthesized in vitro by use of the SP6 promoter/vector system,¹⁵ was carried out as previously described.^{16,17}

RESULTS

Cloning and sequence analysis of β -thalassemic genes. Haplotype analysis of the Mediterranean patient revealed heterozygosity for haplotypes Va and Vb, which differ only at the polymorphic *Hinf* I site 5' to the β gene⁵ (Fig 1). One of the two β -thalassemia genes from this patient was studied earlier by Treisman et al.¹⁰ and was found to contain a G to A transversion at IVS 2 position 1. This mutation abolishes the *Hph* I restriction endonuclease site normally present at the exon 2/IVS-2 junction and is commonly associated with haplotype Vb.⁵ Haplotype Va, on the other hand, is commonly associated with a G to T substitution at IVS-1 position 1. Hybridization studies using synthetic oligonucleotides ruled out the presence of this mutation in the patient's DNA (data not shown). The β -thalassemia gene from the haplotype Va chromosome was cloned and identified by the retention of the *Hph* I recognition site normally present at the IVS-2 donor splice site. Sequence

Fig 1. Results of haplotype analysis in the two patients. Haplotype Va is commonly associated with a G → T substitution at IVS1 position 1; haplotype Vb is commonly associated with a G A substitution at IVS-2 position 1,⁸ and haplotype I is often associated with either a G → A transition at IVS-1 position 110 or β-nonsense 39.

analysis of the promoter region, the three exons, and all intron-exon junctions of this gene revealed, as the only abnormality, a G to T transversion at IVS 1 position 5 (Fig 2).

Haplotype analysis was also performed on a nuclear family of Northern European ancestry. The thalassemia allele was of haplotype I (Fig 1) and was inherited from both parents, who were first cousins, facilitating cloning of the β-globin gene from the homozygous patient. The two most frequent mutations associated with this commonest Mediterranean chromosome background are the G to A transition at IVS-1 position 110 and the β-39 nonsense mutation.⁵ Both mutations were shown, by oligonucleotide hybridization, to be absent in this patient (data not shown), thereby making this gene a candidate for a new mutation. Nucleotide

sequence analysis using synthetic oligonucleotide primers revealed a G to T substitution at IVS-1 nucleotide 5, the same mutation identified in the first patient described above.

Gene transfer and gene expression studies in HeLa cells. Processing of RNA transcribed from the Mediterranean β-thalassemic gene was studied by transfecting in parallel a normal β-globin gene and the thalassemic gene, both cloned in the expression vector πSVplac, into cultured HeLa cells. The cytoplasmic RNA was isolated and subjected to S1 mapping studies using a uniformly labeled single-stranded probe that extends from the promoter of the β-globin gene to the Eco RI site in exon 3¹⁸ (Fig 3A). RNA transcribed from the normal β-globin gene protects a 223-nt fragment corresponding to exon 2 and a 143-nt fragment corresponding to exon 1. The 49-nt fragment corresponding to exon 3 can only be seen on high percentage gels (data not shown). RNA transcribed from the β-thalassemic gene with the G to T mutation at IVS-1 position 5 (IVS1-5^T) protects normal amounts of the 223-nt fragment corresponding to exon 2, decreased amounts of the 143-nt fragment corresponding to exon 1, and two additional fragments, 128 and 105 nt in size. Transfection of HeLa cells with a different cloned β-thalassemic gene containing a G to C mutation at IVS-1 position 5¹⁹ gave a qualitatively similar pattern of S1 nuclease protection (data not shown). A similar pattern was also obtained using reticulocyte RNA from the Mediterranean patient (data not shown), thus demonstrating that the same splicing defects occur in vivo; an additional band of 270 nt was also detected corresponding to the alternatively spliced β-globin mRNA from the patient's other β-thalassemic gene carrying a point mutation at IVS-2 position 1.¹⁰

Splicing at the IVS-1 donor splice site was also evaluated using a 3' end-labeled *Hgi* AI fragment (Fig 3B) as a probe

Fig 2. Side-by-side comparison of the DNA sequence of the Mediterranean β-thalassemic gene from haplotype Va and a normal β-globin gene in the region of the IVS-1 donor splice site. The mutated nucleotide (G) is denoted by (*). The schematic diagram of the β-globin gene shows the position of this mutation at the fifth position of IVS-1. The GT invariant dinucleotides of the donor splice site are underlined.

Fig 3. Analysis of RNA resulting from transient expression of β -globin genes after transfer into HeLa cells. (A) S1 nuclease mapping study of RNA transcribed from the IVS1-5^T β -thalassemic gene and a normal β -globin gene using a uniformly labeled single-stranded probe represented on the schematic map below the autoradiograph. The 223-nt fragment (exon 2) and the 143-nt fragment (exon 1) are seen in the normal (NL) lane. Additional fragments (128 nt and 105 nt) are seen in the IVS1-5^T lane. (B) S1 nuclease mapping of the same RNAs and RNA from the IVS1-5^C gene using a 3' end-labeled probe represented on the schematic map below the autoradiograph. A 90-nt fragment is seen in the NL lane that corresponds to the part of exon 1 complementary to the probe. Both IVS1-5^T and IVS1-5^C lanes show decreased amounts of the 90-nt fragment in addition to three other fragments (102, 74, and 52 nt); a fourth 114-nt fragment of unknown significance is present in all lanes. (C) cDNA products of a primer extension study using RNA from the IVS1-5^T gene or a normal gene (NL) and a primer from exon 2 represented on the map below the autoradiograph. The NL lane shows the expected 226-nt cDNA product, while the IVS1-5^T lane shows decreased amounts of the 226-nt product in addition to two abnormal products (210 and 188 nt).

in another S1 nuclease mapping experiment. The autoradiograph in Fig 3B shows the expected 90-nt fragment when RNA from the normal gene was used and four additional fragments when RNA from the IVS1-5^T gene was used. The 52- and 74-nt fragments correspond to the aberrantly spliced RNAs that generated the fragments of 105 and 127 nt respectively in Fig 3A. These protected fragments result from the utilization of cryptic splice sites at codons 18 and 25 in exon 1.¹⁹ The 102-nt fragment is consistent with the utilization of a cryptic splice site at position 12 of IVS-1.¹⁹ This donor splice site is utilized much less efficiently than the cryptic splice sites in exon 1. The fragment of 114 nt was seen with the normal β gene as well as the β -thalassemic gene. The significance of this fragment is not clear; however, its size is consistent with a splicing event at a cryptic donor splice site at position 24 of IVS-2. A qualitatively similar pattern of splicing was obtained with the β -thalassemic gene containing a G to C mutation at IVS-1 position 5 (IVS1-5^C) (Fig 3B, lane 3). The difference in intensity of the bands between RNA from IVS1-5^T (lane 2) and that of IVS1-5^C (lane 3) is probably due to differences in transfection efficiency of the two genes in the particular experiment shown.

RNA processing was further evaluated by a primer extension study using a 5' end-labeled synthetic oligonucleotide, complementary to the mRNA sense-strand of exon 2, as a

primer in the reverse transcription reaction. The cDNA product of the RNA transcribed from the normal gene is 226 nt in size (Fig 3C). RNA from the IVS1-5^T gene directed the synthesis of cDNA products of 226, 210, and 188 nt in size. The abnormal cDNA products (210 and 188 nt) have sizes consistent with mRNA abnormally spliced at the two cryptic splice sites within exon 1. The minor species thought to result from splicing at the cryptic splice sites within IVS-1 are not visualized in this study.

In vitro splicing in the cell-free extract. To determine the effects of the IVS1-5^T mutation on the in vitro splicing of human β -globin pre-mRNA, we examined both normal and thalassemic SP6 precursors containing exon 1, IVS-1, and exon 2 in the HeLa cell nuclear extract.^{16,17} The results of this analysis are shown in Fig 4. Splicing products and intermediates were identified by comparison with the known species generated from the normal precursor.^{16,17} In addition, splicing intermediates were identified by examining the products generated when the in vitro reaction was carried out in the absence of KCl. Under these conditions only products from the first step of the reaction, exon 1 and the IVS-1/exon 2 lariat, are observed.¹⁶ These analyses revealed that the predominant splicing product generated from the IVS1-5^T precursor is derived from utilization of the cryptic 5' splice site in codon 25 of exon 1. In addition, some normally spliced RNA is observed. However, by contrast with the in vivo

Fig 4. In vitro splicing of normal and IVS1-5^T human β -globin precursors. ³²P-labeled SP6 precursors were synthesized in vitro,¹⁷ spliced in the HeLa cell nuclear extract,¹⁸ and then fractionated on a 5% denaturing polyacrylamide gel. The structures of each of the RNA species are indicated adjacent to the autoradiogram. The boxes refer to exons, and the line indicates the intron. The closed loop indicates the lariat form of the intron. The mutant products and intermediates are designated by an asterisk. The unlabeled faint band seen in lane 2 (also barely visible in lane 1) results from exonuclease degradation of the small amount of uncapped mRNA in the reaction mixture.^{16,17} The sizes of the bands are as follows: unspliced precursor: 497 nt; exon 1/exon 2: 367 nt; and exon 1: 155 nt; the corresponding mutant products are shorter by 16 nt. Lane 1: Normal precursor; Lane 2: Precursor carrying IVS1-5^T mutation, KC1 in the splicing reaction; Lane 3: Precursor carrying IVS1-5^T mutation, KC1 absent from the splicing reaction.

results, no evidence was obtained for utilization in vitro of the cryptic 5' splice site at codon 18. Figure 4 also shows that the splicing efficiency of the thalassemic precursor is less than that of the normal precursor, probably as a consequence of competitive interactions between the normal and mutant 5' splice sites.

To determine whether the normal site of lariat formation, at an adenine residue 37 nucleotides upstream from the 3' splice site, is also utilized when the cryptic 5' splice site is activated, we localized the branchpoint in the mutant IVS-1.

Using the previously developed branchpoint mapping technique,^{17,20} we found that the site of lariat formation occurs at the same position in both the mutant and normal introns (data not shown).

DISCUSSION

The Mediterranean patient studied here has severe transfusion-dependent β -thalassemia major resulting from a profound decrease in β -chain synthesis. One of the two β -globin genes from this patient was studied earlier by Treisman et al¹⁰ and was found to have a mutation that converts the GT invariant dinucleotide of the IVS-2 donor splice site to an AT and thus abolishes normal splicing completely at that site. Haplotype analysis of polymorphic restriction sites in the β -globin gene cluster in this patient revealed heterozygosity for haplotypes Va and Vb. Haplotype Vb is the one commonly associated with the above GT to AT base substitution.⁵ Haplotype Va, on the other hand, is commonly associated with a G to T base substitution at IVS-1 position 1.⁵ Hybridization studies using synthetic oligonucleotides ruled out the presence of the latter mutation in this patient's DNA. DNA sequence analysis of the haplotype Va gene in our patient revealed a G to T transversion at IVS 1 position 5. This mutation is within the consensus sequence of the donor splice site,²¹ a region that is believed to be critical for accurate mRNA splicing.

The second patient in this study differs from the first patient in terms of geographic origins (Northern v Southern Europe) as well as in haplotypes (I v Va; Fig 1) and β -globin gene frameworks (1 v 2).⁴ This patient also differs in that he is homozygous for the mutation, as his parents are first cousins. His clinical phenotype is also typical of transfusion-dependent β -thalassemia major. Despite the difference in chromosome backgrounds, however, both patients have the same mutation of RNA splicing. Both cases represent instances in which the expected mutation/haplotype correspondence was absent. As shown here and emphasized in another survey of seven thalassemia genes,²² this close association of a specific mutation and a particular haplotype is not invariant. Several examples of mutation spread to different ethnic groups, and disparate chromosome backgrounds have been observed and have provided strong evidence for independent origins of the same mutation.^{3,22}

For the β^+ mutation to migrate from haplotype I to Va and framework 1 to 2, a crossing-over event between the mutation and IVS-2 position 74 is required. Occurrence of a recombination event within a short stretch of DNA is less likely than two independent origins of the same mutation in the two ethnic groups. It is of interest that of a relatively small number of β -thalassemia mutations (7 of 37 known mutations) in which recurrences have occurred, two are mutations at the same nucleotide, IVS-1 nt 5.

When we introduced the cloned Mediterranean thalassemic gene into HeLa cells using a transient expression vector and analyzed its mRNA products in S1 nuclease mapping experiments, we demonstrated decreased utilization of the usual IVS-1 donor splice site and utilization of at least three surrounding cryptic splice sites. Two of these cryptic splice sites are in exon 1 of the gene and one is in

Fig 5. Splicing patterns of the β -thalassemic pre-mRNA in intact cells (A) and in the cell-free extract (B). The approximate relative amounts of the different spliced mRNAs are indicated by the thickness of the individual lines.

IVS-1. As illustrated in Fig 5, the majority of the RNA products that accumulated in HeLa cells were spliced at the two cryptic splice sites within exon 1. These cryptic splice sites are also commonly utilized in other β -thalassemic globin genes that carry different mutations within the con-

sensus sequence of the IVS-1 5' splice site,¹⁹ including a β -thalassemia gene isolated earlier from an Asian Indian patient that was shown to have a G to C transition at IVS-1 position 5,²³ the same position that is mutated in the genes from our patients. Splicing of the mutant precursor mRNA in a cell-free extract also revealed decreased utilization of the normal splice site but, in contrast to the results in intact cells, only one of the cryptic sites in exon 1 was utilized (Fig 5). Similar differences in the relative amounts of spliced RNAs obtained from cryptic sites have been observed with most of the other thalassemia mutants that have been analyzed both in vivo and in vitro.^{16,17,20,23} This may be due to differences in the concentrations of the various factors in intact cells compared to that in the in vitro extracts.²⁴

ACKNOWLEDGMENT

We thank Elaine Coupal for skilled technical assistance and Drs Robert Hart and George Honig for providing blood samples for study from their patient.

Endothelial Cell Interactions With Sickle Cell, Sickie Trait, Mechanically Injured, and Normal Erythrocytes Under Controlled Flow

By Gilda A. Barabino, Larry V. McIntire, Suzanne G. Eskin, David A. Sears, and Mark Udden

Increased adhesive forces between sickle erythrocytes and endothelial cells (EC) have been hypothesized to play a role in the initiation of vasoocclusion in sickle cell anemia. Erythrocyte/human umbilical vein EC interactions were studied under controlled flow conditions for normal (AA), homozygous sickle cell (SS), sickle cell trait (AS), mechanically injured normal, and "high-reticulocyte control" RBC by using video microscopy and digital image processing. The number of adherent RBC was determined at ten-minute intervals during a washout period. Results indicate that SS RBC were more adherent than AA RBC. Mechanically injured (sheared) AA RBC were also more adherent than control normal cells but less adherent than SS RBC. AS RBC did not differ significantly in their adhesive properties from normal RBC. Less-dense RBC were more adher-

ent to EC than dense cells for normal, SS, and high-reticulocyte control RBC. The number of cells adherent at a given time during washout was a very strong function of wall shear rate. In addition, at all shear rates studied, the average velocity of individual SS RBC in the region near the EC surface was approximately half that of AA RBC at the same bulk volumetric flow rate through the flow chamber. These findings suggest that the increased adhesion of sickle RBC is at least partially related to the increased numbers of less-dense RBC present. Increased adherence of the less-dense cells to the EC lining vessel walls could contribute to microvascular occlusion by lengthening vascular transit times of other sickle cells.

© 1987 by Grune & Stratton, Inc.

RBC-ENDOTHELIAL CELL (EC) interactions may be important in the vasoocclusive phenomena observed in sickle cell disease. Evidence has been presented by several investigators that suggests that sickle cells adhere abnormally to EC under static conditions as well as under uncontrolled conditions of flow.¹⁻⁶ The abnormal adherence of sickle cells has been correlated with the vasoocclusive severity of the disease.⁷ Interactions between blood cells and endothelial surfaces in blood vessels occur under dynamic conditions. Flow inhibition or promotion of blood cell adhesion to the endothelium may occur depending on the velocity and morphology of the moving cells. Presumably, cells in the vicinity of the endothelium that are moving slowly would have a greater chance of making contact and interacting with the endothelial surface.

Altered flow characteristics of sickle blood under both oxygenated and deoxygenated conditions have been reported in microvascular studies using intravital microscopy techniques.^{8,9} LaCelle¹⁰ reported that adherence of sickle cells to endothelium occurred at low flow rates. Klug and Lessin⁸ reported that sickle RBC adherence to the vessel wall did not occur at moderate and high flow rates. The mean transit time of sickle RBC was higher than that for normal RBC during their passage through the coronary circulation. In a rat mesocecum microvascular preparation,¹¹ it appeared that the cells actually trapped are mainly the dense sickle RBC.

The shear rate (flow rate) is an important dynamic variable present in vivo that will affect the propensity of

erythrocytes to adhere to the vessel wall. In the studies described later, we consider the case of laminar flow between two parallel surfaces as a simplified model of a blood vessel. In this case, movement of fluid in the direction of the applied pressure gradient results in the development of a velocity gradient within the fluid. The velocity gradient, or shear rate, is defined as the difference in velocity between two adjacent layers of moving fluid divided by the distance between them and has the units (cm/s)/cm, or "inverse seconds" (s^{-1}). Time average wall shear rates vary throughout the circulation and range from 0 to 5,000 s^{-1} . The highest values occur in the arterioles and microcirculatory vessels and the lowest values in the small venules and veins. There is a rapid drop in the average vessel wall shear rate as a cell exits the capillaries and enters the venules. Using a jet shearing technique, Smith and LaCelle¹² have recently shown that the number of sickle cells adherent to cultured endothelium decreased as the wall shear rate produced by the fluid flow was increased after a 30-minute static incubation.

In our studies, the effect of wall shear rate on the adhesion of RBC to EC was examined under controlled flow conditions. Velocity gradients utilized in these experiments approximate those found in venules, which are probably important sites for adhesive events. Leukocyte margination in vivo is usually seen to occur in this part of the circulation. Fluid drag forces on attached cells (related to the wall shear rate) are quite low in these vessels. Videotaped experiments were analyzed by using digital image analysis techniques to determine the velocities of individual sickle and normal RBC in the vicinity of a cultured human endothelial cell monolayer.

MATERIALS AND METHODS

Blood was drawn into heparinized tubes from patients with homozygous sickle cell disease (SS), volunteers with sickle cell trait (AS), other patients with high reticulocyte counts ("high-reticulocyte controls"), and normal subjects (AA). After centrifugation at 1,000 g for ten minutes, the plasma and buffy coat were removed. The RBC were washed three times with medium 199 supplemented with 20% fetal calf serum (FCS, Hyclone Tissue Culture Products, Logan, UT), 100 U/mL penicillin, and 100 μ g/mL streptomycin and then suspended at the desired hematocrit in the supplemented medium. For experiments involving density-fractionated RBC, cells

in plasma were separated into density fractions by centrifugation at 30,000 g for one hour at 30°C in an angle rotor.¹³ The column of RBC was separated into five equal fractions. Sheared RBC were obtained by subjecting suspensions of cells to a subhemolytic shear stress of 1,500 dyne/cm² for two minutes in a Rice University concentric cylinder viscometer described previously.¹⁴⁻¹⁶

Endothelial cell cultures. Human umbilical vein EC were harvested from umbilical cords by using culture procedures adapted from those of Gimbrone et al¹⁷ and grown to confluence on glass slides. To remove the EC, the veins were cannulated, rinsed with 100 mL phosphate-buffered saline (PBS) and then filled with 0.03% collagenase in PBS and incubated for 30 minutes at room temperature. After incubation, the enzyme solution was flushed through the cord with 100 mL PBS, and the effluent was collected and centrifuged at 100 g for ten minutes. The cell pellet was resuspended in medium 199, supplemented with 20% FCS and antibiotics, and seeded onto 75 × 38-mm glass slides (Fisher, Medford, MA) that had been pretreated with 0.5 mol/L NaOH for two to three hours and rinsed. Cultures were incubated at 37°C and became confluent after three to four days. Experiments were conducted within four days after the cultures reached confluency. Identification of the monolayer as EC was obtained by positive immunofluorescent staining for factor VIII-related antigen and by morphological assessment. Viability was assessed by trypan blue exclusion.

RBC-EC adherence assay. EC monolayers on glass slides formed the base of a modified Richardson flow chamber that was mounted in a video microscopy system on the microscope stage (Fig 1). The chamber depth was controlled by the thickness of the gasket, and for the experiments presented here, was machined to either 170 μm or 104 μm. RBC suspensions at a 1% hematocrit were perfused into the chamber for five to ten minutes at a constant flow rate (wall shear rates varied from 25 to 500 s⁻¹) followed by a 20-minute rinse with cell-free suspending medium at the same flow rate. In some experiments, a ten-minute incubation period without flow preceded the rinse, during which time the RBC were allowed to settle onto the EC monolayer. Perfusion was achieved with a Harvard syringe

pump. The red cell suspensions were maintained in a 37°C water bath, and the chamber was maintained at 37°C by an air curtain incubator. The number of adherent RBC was determined at 1, 10, and 20 minutes of rinse for the same single microscope field. After 20 minutes of rinse, multiple microscope fields were examined. The initial count was made after static incubation and a one-minute period of rinsing to remove nonadherent settled cells. In the continuous-flow experiments where the incubation period was eliminated, the rinse immediately followed the RBC perfusion, and the number of adherent RBC was determined at ten and 20 minutes for the same microscope field. A video camera (RCA TC 1005; Lancaster, PA) mounted to a Nikon Diaphot microscope was used to record and display experiments. Experiments were recorded on video tape (Gyr TL 2001; Anaheim, CA) for later playback and analysis and displayed on a high-resolution TV monitor.

The wall shear stress in the flow chamber was calculated by using the momentum balance for a newtonian fluid and assuming a parallel-plate geometry and fully developed flow. In easily measurable experimental quantities, it is given by the formula $\tau = 3\mu Q / 2a^2b$ dynes/cm² (wall shear stress) where Q is the flow rate, cm³/s; μ is the fluid viscosity, dynes · s/cm²; $2a$ is the gap width (chamber depth), cm; τ is the wall shear stress, dynes/cm²; and b is the slit width, cm.

The wall shear rate ($\dot{\gamma}_w$) is given by $\dot{\gamma}_w = 3Q / 2a^2b$ (s⁻¹).

Velocity determination using image analysis. Taped experiments were analyzed by using a digital image processor (Model 327; Perceptive Systems Inc, Houston) for image quantification. To determine the velocity of individual cells, sequential images separated by a given delay time were digitized from tapes. The position of a particular red cell was noted in each digitized frame, and the velocity was determined from the number of pixels (picture elements into which a digitized frame is divided) a cell had moved between frames for the given delay time. All velocities were converted to micrometers per second by using a calibration on the microcomputer. Velocity measurements were made during the cell perfusion before the rinse cycle was initiated. At least 200 cells were tracked at each shear rate and results presented as a velocity histogram. For a given video frame, all nonadherent cells in focus near the EC surface were automatically tracked and entered into the histogram.

Statistical methods. The data of multiple microscope fields after 20 minutes of rinse were analyzed by using an f test that distinguishes between the treatment variance (different blood samples, eg, HbAA, HbSS, HbAA [high-reticulocyte], or HbAS sheared) and the variances due to the random or uncontrolled variables (different donors, different EC monolayers, field-to-field variances within a monolayer, etc). For comparisons of several single field measurements at different times (1, 10, and 20 minutes of washout) the Student's t test was used.

RESULTS

When examined under flow conditions after a static ten-minute incubation period, sickle RBC were more adherent to EC than normal RBC (Table 1). A larger fraction of settled RBC remained adherent for SS RBC (1%) than for AA RBC (0.16%) after one minute of rinsing. These percentages are the ratio of adherent cells after one minute of rinse (Table 1), divided by the cell density of the initial monolayer of RBC in contact with the endothelium after static incubation, and multiplied by 100. RBC from individuals with AS did not differ significantly from normal RBC in their adhesion to EC. Mechanically traumatized (sheared) RBC, both normal and sickle trait, were also more adherent than normal RBC, but not as adherent as sickle RBC. Results from

Fig 1. Schematic diagram of the adherence apparatus consisting of a flow chamber with a rectangular Silastic gasket and a glass slide with the attached endothelial monolayer. These are held together by a vacuum maintained at the periphery of the slide, forming a channel of parallel-plate geometry. The height of the flow channel (gap width) is controlled by the thickness of the gasket. RBC suspensions and culture medium enter and exit the channel through two slits machined in the polycarbonate plate. Flow is controlled by using the Harvard syringe pump. The chamber is mounted on an inverted microscope equipped with a video camera. For chambers used in these experiments, the range of wall shear rates possible is 0 to 5,000 s⁻¹, covering most of the range of physiological interest.

Table 1. Adhesion of Normal, Sickie, Sickie Trait, and Sheared RBC to EC at a Wall Shear Stress of 1 dyne/cm²

RBC	No. of Donors	Adherent RBC/mm ² at Rinse Times		
		1 min	20 min	Multiple Fields at 20 min
AA (n = 19)	8	24.78 ± 16.46	8.11 ± 5.28	6.62 ± 6.10 (s = 284)
SS (n = 13)	4	165.70 ± 142.62	52.56 ± 44.08	39.32 ± 29.72 (s = 211)
AS (n = 2)	1	10.41	8.33	9.25 ± 8.25 (s = 32)
AA sheared (n = 10)	6	40.83 ± 11.42	17.08 ± 8.66	22.25 ± 13.46 (s = 165)
AS sheared (n = 2)	1	29.16	16.66	17.16 ± 9.04 (s = 32)

NOTE. In these experiments, there was a ten-minute incubation period before the rinse was begun. The flow chamber gap width was 170 μm . The data at the one- and 20-minute rinses represent the means of single fields counted in *n* experiments. The data in the far right column reflect the sum of multiple fields counted in each experiment after a 20-minute rinse (*s*, total fields in all *n* experiments). The differences between the AA controls and the SS, AA sheared, and AS sheared RBC had a level of significance of $P < .01$ (*f* test for multiple fields at 20 minutes and Student's *t* test for single fields at 20 minutes) after 20 minutes of rinse. There was no significant difference between the adhesion of AA and AS RBC.

experiments performed using RBC from a splenectomized patient with HbAA indicated that these RBC behaved like normal cells with respect to adhesion to EC (data not shown).

Experiments on density-separated sickle, normal, and high-reticulocyte control RBC revealed that the least-dense fraction (fraction with the highest percentage of reticulocytes) was more adherent than the denser fractions and the unfractionated sample (Table 2). The high-reticulocyte control RBC were more adherent than normal, which suggested that the degree of adhesion may be partially related to the percentage of young cells in the cell population.

The same differences in adhesion between the RBC populations were noted when the ten-minute incubation period was eliminated so that the entire experiment was conducted under flow conditions (Table 3). Under conditions of continuous flow a smaller chamber gap width was utilized, thereby reducing the total flow area and increasing the potential for RBC-EC interactions. In the data presented in Table 3, the flow rate was decreased so that the smaller gap width maintained the same wall shear stress of 1 dyne/cm² (wall shear rate of 100 s⁻¹).

To determine the dependence of sickle and normal RBC adherence to EC on the wall shear rate, experiments were performed at shear rates ranging from 25 s⁻¹ to 500 s⁻¹. The RBC adherence after the 20-minute rinse period as a function of wall shear rate is plotted in Fig 2. For both sickle and normal RBC, adhesion decreases as shear rate increases.

Little or no adhesion is observed after 20 minutes of washout at shear rates exceeding 170 s⁻¹ for normal RBC and at shear rates exceeding 260 s⁻¹ for sickle RBC. The difference between normal and sickle cell behavior with respect to adhesion appears to be more pronounced at the lower shear rates.

Typical velocity distributions of sickle and normal RBC obtained from video tapes at two specific wall shear rates are plotted in Figs 3 and 4 in terms of the percentage of total nonadherent RBC in the frame traveling in a particular velocity range. At each shear rate (flow rate), it is apparent that a higher proportion of sickle RBC are traveling at slower velocities—whereas a higher proportion of normal RBC are traveling at the higher velocities. Sickle cells move more slowly across the endothelial surface than normal cells. The average velocity of all of the near-wall nonadherent cells in a given frame was usually at least twice as high for normal RBC as it was for sickle RBC at the same bulk volumetric flow rate.

DISCUSSION

Shear rate plays an important role in determining the rheological interactions of sickle cells in the circulation, particularly at the small vessel level (arteriole, capillary, venule). In cell filtration studies, the relative resistance to flow offered by both oxygenated and deoxygenated SS cells is much lower when the flow velocity is high.¹⁸ At low shear

Table 2. Effect of Cell Density on Normal and Sickle Cell Adherence to EC After a 20-Minute Rinse at a Wall Shear Stress of 1 dyne/cm²

	SS			AA (High-Reticulocyte)		AA	
	ISC (%)	Reticulocytes (%)	Adherent RBC*	Reticulocytes (%)	Adherent RBC*	Reticulocytes (%)	Adherent RBC*
Whole	16.9	16.1	87.75 ± 17.88	8.4	38.54 ± 19.54	0.8	6.25 ± 3.42
Top	9.6	33.2	92.42 ± 31.58	15.0	48.96 ± 13.83	3.3	11.17 ± 6.54
Middle	22.6	6.7	52.63 ± 11.67	6.0	22.13 ± 6.92	0.6	5.71 ± 2.58
Bottom	28.6	8.7	51.29 ± 13.29	1.0	22.92 ± 7.88	0.6	8.83 ± 4.00

NOTE. In these experiments, there was a ten-minute static incubation period before the rinse was begun. The flow chamber gap width was 104 μm . The data are from a representative experiment for each RBC type. AA (high-reticulocyte) RBC were obtained from an iron-deficient patient responding to treatment. The differences between normal AA and the SS and AA (high-reticulocyte) RBC had a level of significance of $P < .0005$ (using the *f* test) for whole blood samples. For fractionated samples, there was no significant difference between the adhesion of middle and bottom cells, but the differences between the top and middle and the top and bottom cells had a level of significance of $P < .0005$ for SS and AA (high-reticulocyte) RBC.

Abbreviation: ISC, irreversible sickled cells.

	10 min	20 min	Multiple Fields at 20 min
AA (n = 12)	14.77 ± 6.49	11.36 ± 8.16	11.48 ± 6.83 (s = 176)
SS (n = 12)	88.98 ± 22.56	59.09 ± 35.08	45.12 ± 26.76 (s = 164)
AA (sheared) (n = 6)	22.92 ± 9.85	20.14 ± 6.55	20.65 ± 7.80 (s = 95)
AA (high reticulocyte)* (n = 5)	80.46 ± 32.64	49.81 ± 18.82	43.71 ± 23.59 (s = 76)

NOTE. In these experiments, there was no static incubation period before the rinse was begun. The flow chamber gap width was 104 μm , and the wall shear stress was 1 dyne/cm². The data at the ten- and 20-minute rinses represent the means of single fields counted in n experiments. The data in the far right column reflect the sum of multiple fields counted in each experiment after a 20-minute rinse (s, total fields in all n experiments). The differences between the AA control and the SS, AA sheared, and AA (high-reticulocyte) RBC all had a level of significance of $P < .0005$ (using the *t* test) for multiple fields at 20 minutes. For single fields at 20 minutes using the Student's *t* test, $P < .0005$ for AA v SS and AA v high-reticulocyte AA, whereas $P < .025$ for AA v sheared AA.

*AA (high-reticulocyte) RBC were obtained from two donors, a patient responding to treatment for iron deficiency and a patient with hereditary spherocytosis.

rates, significant problems may develop in the microcirculation due to obstructed flow caused by sickle cells becoming stiff and/or by SS cells interacting with EC. In a recent report, Rodgers et al¹⁹ presented evidence that microcirculatory flow in patients with sickle cell disease is periodic. The increased adhesion of sickle cell RBC to microvascular or venule endothelium may be a rheological factor that contributes to local flow disturbance and induces oscillation. On the other hand, the high local shear stresses obtained in oscillatory flow could facilitate the passage of red cells through small vessels by helping them to deform and may dislodge sickle cells already adherent to the endothelium. Less-dense sickle RBC, which appear to be more adherent than heavier cells, may play a role in initiating vasoocclusion by sufficiently retarding microvascular flow to extend the transit times of more-dense upstream cells beyond the delay time required for gel formation. This phenomenon may be particularly important in the venules where the chances for adhesive events are increased because of the low shear rates involved and where cell transit times may be approaching the pregelation times for heavier sickle cells. In this case, extending transit times even slightly could result in increased

polymer content and sickling. Recent reports have shown that polymer fraction may be correlated with vasoocclusive severity,²⁰ though not in all cases.²¹ Whether interactions between sickle erythrocytes and vascular EC are significant enough to play a role in the obstruction of flow would be influenced by the wall shear rate. Results from our studies suggest that adherence of sickle cells is enhanced at low shear rates but is not very different from that of normal RBC at high shear rates (where long-term adherence to endothelium for all RBC is very low).

Digital image analysis techniques were used to analyze videotaped flow experiments to gain insight into dynamic RBC-EC interactions by determining the velocities of individual sickle and normal RBC. The velocity of cells plays an important role in the promotion or inhibition of cell adhesion. Because of the inward radial migration and wall exclusion of RBC, which are important in flow channels whose height is many times that of the red cell, most of the RBC in a suspension will be flowing at relatively high speed in the core of the channel. Erythrocytes that are traveling in the cell-poor region near the wall are actually moving at different rates that, in some cases, may be slow enough to allow adhesive interactions to take place between the RBC and the

Fig 2. Effect of shear rate on adherence of sickle and normal RBC to EC after 20 minutes of washout at a fixed wall shear rate. The chamber used for these studies was the same as described in Table 3, and all experiments were done under continuous flow (no incubation). Data points are means with SD. (●), SS; (▲), AA.

Fig 3. Velocity distribution for sickle and normal RBC near the EC monolayer at a wall shear rate of 126 s⁻¹. Cells moving at less than 1 $\mu\text{m/s}$ were not included in the distribution because they were considered to be adherent. More than 200 individual cell velocities were obtained for both SS and AA samples. The average velocities were 60.2 $\mu\text{m/s}$ for SS RBC (▨) and 121.7 $\mu\text{m/s}$ for AA RBC (□).

Fig 4. Velocity distributions for sickle and normal RBC at a wall shear rate of 50 s^{-1} . The flow chamber and number of cells tracked were the same as in Fig 3. The average velocities were $14.2 \mu\text{m/s}$ for SS RBC (▨) and $43.4 \mu\text{m/s}$ for AA RBC (□).

EC lining the vessel wall. From qualitative observations of videotaped experiments, sickle RBC traveling near the EC surface appeared to be moving more slowly than normal RBC near the EC surface for a given bulk volumetric flow rate. Quantitative velocity measurements presented earlier utilizing digital image processing confirmed these observations. Some red cells (particularly in the case of sickle RBC) appeared to be sliding slowly across the endothelial surface as if temporary contacts between the cell surfaces were being made but were not strong enough for the red cell to adhere. Differences in the adherence properties of sickle and normal RBC (sickle RBC may be more "sticky") could account for the slower velocities of sickle RBC near the EC monolayer.

The increased adhesion of less-dense normal and high-reticulocyte control RBC suggests that the increased adhesive properties of SS RBC may be, at least in part, a reflection of their young mean age. However, other factors may be involved. Mechanical damage of the red cell can also lead to increased RBC/EC adhesion as shown by our results with sheared normal RBC (Tables 1 and 3). Several investigators have shown that sickle RBC are much more susceptible to shear damage than normal cells^{22,23} and that hemolysis can occur at stress levels that are obtained physiologically. Sublytic mechanical damage to sickle cells in the circulation may also predispose them to increased EC adherence.

Exposure of normal RBC to subhemolytic shear stresses is known to induce a deformability defect and lead to calcium accumulation without alterations in morphology.¹⁴⁻¹⁶ After sublytic shear stress exposure, both AA and AS RBC were

more adherent to EC than normal RBC. Further study of these stressed cells may aid in determining the characteristics of the SS RBC that make them more adherent.

Plasma factors have been shown to influence sickle RBC adhesion.^{3,5} Results obtained in this study indicate that adhesion differences between erythrocytes can be demonstrated in the absence of specific human plasma factors peculiar to SS plasma because these experiments utilized washed red cells and a tissue culture suspending medium. Specific SS plasma factors may play a modulating role in the adhesion process but were not necessary to demonstrate altered adhesion in sickle RBC in our system.

Previous experimental evidence has suggested at least two phenomena that may predispose to vasoocclusion in sickle cell disease: (a) intracellular gel formation, which leads to shape change and decreased deformability of SS RBC,²⁴ and (b) increased adhesion of SS RBC to EC.¹⁻⁶ In this study, the adhesion process was examined under controlled fluid mechanical conditions to gain insight into events that may lead to vasoocclusion but do not directly involve the deformability of the SS RBC. Cells with maximum intracellular gel formation and shape change are the most-dense cells,^{25,26} whereas our studies indicate that the most-adhesive cells are the least-dense RBC. Although the least-dense cells are hemodynamically the most competent in deoxygenated blood,²⁶ their tendency to adhere could sufficiently retard flow in the small vessels to extend transit times for other cells beyond the critical delay time required for gel formation. The delay time for HbSS gelation is strongly dependent on the intracellular hemoglobin concentration. Thus, dense cells with high mean corpuscular hemoglobin concentrations may have a profound effect on the microcirculatory flow if their capillary transit times are increased. The adhesion of light (young) cells may lengthen transit times for other cells in the microvasculature, thereby leading to gel formation in dense cells and resulting in vasoocclusion. Recently, increased adhesion of reticulocytes in SS disease to fibronectin-coated Petri dishes has been demonstrated in a static system.²⁷ The abnormal adherence of young cells may be of little or no consequence in other diseases that are characterized by increased numbers of reticulocytes but do not involve vascular occlusive events. Increasing capillary transit times would not result in changes in the rheological properties of RBC for these diseases. Increased adherence to endothelial cells, the only factor besides delay time thought to be correlated with disease severity, may be an important feature of young RBC in sickle cell disease.

Erythrocyte Membrane Skeleton Abnormalities in Severe β -Thalassemia

By E. Shinar, O. Shalev, E.A. Rachmilewitz, and S.L. Schrier

The protein composition of ghosts, inside-out vesicles (IOV), and membrane skeletons (MS) of erythrocytes (RBC) from splenectomized (spx) and nonsplenectomized (non-spx) patients with β -thalassemia major and β -thalassemia intermedia was determined. Ghosts from spx thalassemia intermedia patients had a significant increase in their globin content (which was mostly heme reactive) and contained extra polypeptides in the protein 4.2 to 5 and 6-globin areas. The Triton-extracted MS from all of the thalassemic patients showed two major abnormalities: (a) they retained up to twice the amount of protein 3 when compared with controls; (b) they had a significant increase in their globin content, the concentration of which was independent of their protein 3 content. Analysis of the IOV revealed no differences between those prepared from

normal controls and those of the patients. MS from spx thalassemia intermedia patients were grossly abnormal when examined by scanning electron microscopy and they exhibited aggregates of material that on transmission electron microscopy suggested the presence of globin precipitates. We propose that, although the integral protein composition, as reflected in the IOV, from severely affected β -thalassemics is intact, their MS assembly is deranged. The altered skeletal structure of thalassemic RBC could result from attachment of denatured globin to the skeleton components. These abnormalities may contribute to the premature cell death seen in severe β -thalassemia.

© 1987 by Grune & Stratton, Inc.

THE THALASSEMIA are a group of inherited disorders in which globin chain synthesis is impaired. Although the genetic defects of β -thalassemia have been studied intensively¹ the reasons leading to the premature removal of the abnormal RBC in the marrow and from the peripheral circulation are not clearly understood. It has been proposed that the extra, unmatched α -globin chains precipitate in the RBC, resulting in alteration of normal structure, function, and deformability of the membrane.² These changes, when expressed at the RBC exterior, perhaps by reverse transmembrane signaling, might indicate to the macrophagic system that these cells should be removed. Indeed modification of the external membrane surface has recently been found.³ There is also evidence of more widespread membrane dysfunction in β -thalassemia. Morphological changes in the membranes of thalassemic RBC have been documented in ultrastructural studies of mature as well as nucleated cells.^{4,5} Moreover, membranes of thalassemic RBC are known to be more sensitive to oxidant stress, as reflected by an increase in malonyldialdehyde formation, a decrease in polyunsaturated fatty acid levels,⁶ an increase in protein cross-linking,⁷ and a decrease in titratable membrane thiols.⁸

In this study we tried to identify alterations of the β -thalassemic RBC membrane that might be produced by precipitation of excess unmatched α -globin chains at the

cytosolic surface of the membrane. Accordingly, we analyzed the polypeptide composition of isolated hypotonic white ghosts from severely affected but untransfused patients with β -thalassemia intermedia and transfused patients with β -thalassemia major. We then resolved the membrane into its component parts by studying its peripheral protein membrane skeleton (MS), as reflected in Triton-extracted cytoskeletal shells,⁹ and the integral membrane proteins, as reflected in inside-out vesicles (IOV) prepared from the same RBC.

MATERIALS AND METHODS

Patients Studied

Samples of heparinized venous blood were collected from a total of 18 patients with β -thalassemia intermedia, five patients with β -thalassemia major, five patients with other hemoglobinopathies, and four nonhemoglobinopathic reticulocyte-rich patients as well as 14 normal splenectomized and nonsplenectomized subjects under protocols approved by the Hadassah Hospital Committee on Human Experimentation and the Stanford Committee on Human Experimentation. The majority of the thalassemic patients were of either Kurdish-Jewish or Israeli-Arabic extraction. Eleven of the 18 patients had been splenectomized (spx) several years prior to the present study whereas the rest were nonsplenectomized (non-spx). Initially samples were studied in Jerusalem within 24 hours after blood collection. In order to confirm reproducibility, to apply more stringent inhibition of proteolysis, and to utilize newer methods of quantifying polypeptide composition, most patients were restudied at Stanford. Heparinized whole blood samples arrived at Stanford within 36 hours after being drawn. Upon arrival they were washed, and the buffy coat was removed. The hematocrit value was brought to 50% with isotonic saline, to which 2 mmol/L diisopropyl fluorophosphate (DFP) and 10 μ g/mL of pepstatin A and of leupeptin were added to prevent proteolysis. The thalassemia intermedia patients rarely required blood transfusions, and none had been transfused 2 to 3 months prior to study. The thalassemia major samples were obtained just prior to the next transfusion, typically 4 weeks after the last transfusion. Each sample was not subjected to all of the analyses eventually used. The detailed hemoglobin and globin chain synthesis ratios of most of the patients have been previously reported.¹⁰

Preparation of Ghosts and Membrane Fractions

White ghosts were prepared by lysis of RBC in hypotonic phosphate buffer according to the method of Dodge et al.¹¹ The lysis

buffer contained 1 mmol/L EDTA and 0.1 mmol/L phenylmethylsulfonyl fluoride to inhibit protease activity (0.2 mmol/L DFP was used for the shipped samples). Ghosts prepared from the spx thalassemia intermedia patients retained a brownish color despite extra washes with 40-fold volumes of lysis buffer. IOV were prepared by incubating white ghosts in 0.5 mmol/L sodium phosphate buffer (pH 8) at 0°C for one hour and then harvesting them at the interface of a Dextran T-500 barrier (Pharmacia Fine Chemicals, Piscataway, NJ) by centrifugation in a Spinco SW41 rotor (Spinco-Beckman, Palo Alto, CA) for two hours at 40,000 rpm.¹² MS were prepared by direct lysis of intact RBC (pretreated both in Jerusalem and Stanford with 2 mmol/L DFP, 10 µg/mL pepstatin A, and 10 µg/mL leupeptin) with Triton X-100 at a concentration of 25 mg/mL packed RBC as described by Sheetz.¹³ Since considerable care is necessary in standardizing this preparation, the Triton was weighed out, and duplicate microhematocrits were performed on the packed RBC to insure that the ratio of Triton to RBC volume was tightly controlled. The MS were extracted by using both isotonic and hypertonic 0.3 mol KCl buffer. To control proteolysis further the extraction buffers and sucrose gradients contained 0.25 mmol/L DFP, 10 µg/mL pepstatin A, and 10 µg/mL of leupeptin. The addition of hypertonic KCl removed considerably more integral proteins and produced MS containing substantially less protein 3.¹³ The amount of protein 3 retained in these MS was calculated as a percentage of the total protein after subtracting the globin and protein 6-globin content in each sample to provide a more equivalent denominator for comparative purposes. On several occasions, cellulose fiber columns were used to remove the WBC and platelets.¹⁴ No differences in the results were found when this time-consuming step was used, and therefore it was not used routinely.

When it became apparent that MS from spx β -thalassemia intermedia RBC contained more globin than the non-spx MS, it was important to determine whether that globin was firmly adherent to the MS or simply reflected aggregates of globin enmeshed or trapped in the cytoskeleton at the time of Triton skeleton formation. To explore this possibility, MS from spx β -thalassemics were frozen once at -20°C and then thawed by warming up to room temperature slowly. Aliquots were set aside, and the remainder was sonicated for three to five minutes at output control 3 in the probe sonicator Ultrasonics, Inc. Model W-220 (Orangeburg, NY). All samples were then recentrifuged at 100,000 g for 60 minutes, and the pellets were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) as will be described later.

Protein Determination

Protein was determined by the Bradford method,¹⁵ with bovine serum albumin as a standard, and by the method of Lowry et al.¹⁶ In an attempt to distinguish free globin from heme-containing globin, the hemoglobin content of the several membrane preparations was determined in Jerusalem by using the benzidine reaction.¹⁷

SDS-PAGE

Samples were separated on 6% to 18% nonlinear gradient slab gels according to the method of Laemmli.¹⁸ The gels were stained with Coomassie blue or PAS reagent. In Jerusalem the gels were scanned and analyzed in an automated standardized Helena Quick Quant II densitometer (Helena Laboratories, Beaumont, TX). The area occupied by each band was determined with a recording integrator. The protein composition of the gels of the samples studied at Stanford was determined by the method described by Agre et al.¹⁹ Briefly, Coomassie blue-stained bands were cut out, eluted with 1 mL of 25% pyridine, and the absorbance at 605 nm was measured. This method yielded reproducible quantitation of the spectrin:protein 3 ratios and supported the densitometric determinations.

Immunoreactive Spectrin

To determine whether some of the polypeptide bands that appeared in excess in the thalassemic ghosts and MS were products of proteolytic attack on spectrin we used the technique of Western immunoblotting. Proteins from SDS-PAGE were transferred to nitrocellulose paper exactly as described by Towbin et al.²⁰ Then after unoccupied sites were covered with albumin, the nitrocellulose was reacted with our polyclonal-monospecific rabbit antispectrin antibody,²¹ and the sites of binding were identified by the immunoperoxidase reaction.²² Screening studies had established that with the use of this technique our monoclonal mouse antispectrin antibody reacted only with β -spectrin,²³ whereas the rabbit polyclonal antibody reacted only with α - and β -spectrin at a ratio of roughly 80:20. These studies were done only on the samples sent to Stanford.

Electronmicroscopic Studies

Both white ghosts and MS were examined by transmission electron microscopy (TEM) in a Philips EM-300 electron microscope (Philips, Mahwah, NJ) after fixing with a 2% solution of glutaraldehyde in phosphate-buffered saline and then embedding and sectioning.²⁴ Studies by the scanning electron microscope (SEM) were performed after processing of the samples according to the method of Sanders et al.²⁵ using a Jeol-35 scanning electron microscope (Jeol USA, Inc. Peabody, MA).

Statistical Analysis

Statistical analysis was carried out using the Abstat program (Abstat-Anderson-Bell Co, Canon City, CO) for the IBM-PC (IBM, Boca Raton, FL).

RESULTS

Polypeptide Analysis

Hypotonic ghosts. In the spx thalassemia intermedia ghosts studied at Stanford there was an increase in the globin content that reached $13.7\% \pm 3.5\%$ (mean $\pm$ S.D.) of the total amount of protein compared with $3.0\% \pm 1.6\%$ and $4.7\% \pm 2.7\%$ in the non-spx thalassemics and normal controls, respectively ($P < .0001$) (Table 1, Fig 1). Studies performed in Jerusalem yielded similar results ($8.9\% \pm 0.7\%$, $3.7\% \pm 0.2\%$, and $2.9\% \pm 1.0\%$, respectively). The benzidine reaction performed on the samples in Jerusalem showed that the majority of this membrane-associated globin was heme containing ($8.2\% \pm 4.4\%$, $3.8\% \pm 2.8\%$, and $2.9\% \pm 1.2\%$, respectively). In addition, extra polypeptides appeared in the ghosts from spx thalassemia intermedia patients in the areas between proteins 4.2 to 5 and 6-globin. The increase in the 4.2 to 5 area was significantly greater in spx patients than in the comparable controls ($P = .03$), but there was no significant difference between controls and non-spx thalassemics ($P = .3$). The increase in the 6-globin area in spx patients was significantly greater than either controls ($P = .0003$) or non-spx thalassemics ($P = .0006$); however, there was no significant difference between controls and non-spx thalassemics ($P = .26$). Although the changes in polypeptide pattern in the 4.2 to 5 area and the 6-globin area seem to be present in other hemoglobinopathies as well, the increase in globin content was highest in the spx β -thalassemics. The spectrin:protein 3 ratio was slightly lower in the spx thalassemics than in either

Table 1. Analysis of SDS-PAGE of Ghosts of Thalassemia Intermedia Patients and Controls

	Spectrin/ Protein 3 Ratio	Globin*	4.2-5*	6-Globin*
Normal controls (6)	1.35 ± .10	4.7 ± 2.7	9.5 ± 2.1	5.7 ± 1.3
Thalassemia intermedia, non-spx (7)	1.32 ± .20	3.0 ± 1.6	10.9 ± 2.9	6.7 ± 1.7
Thalassemia, spx (11)	1.15 ± .16	13.7 ± 3.5	11.9 ± 2.0	13.0 ± 3.6
Other hemoglobinopathies				
Sickle cell anemia				
A	1.1	7.4	14.7	12.2
B	1.1	6.1	12.9	11.5
C	1.0	6.1	15.2	14.6
Hgb SC	1.4	6.2	11.3	8.2
Hgb AC	1.5	3.9	9.9	9.6

NOTE. Numbers in parentheses are the number studied.

*Expressed as a percentage (mean ± SD) of the total protein.

controls ($P = .01$) or non-spx thalassemics ($P = .05$), and there was no difference between controls and non-spx thalassemics ($P = .7$). Immunoblot analysis indicated that in the ghosts of each of the spx thalassemic patients there was a very faint band in the protein 7 area that reacted with antispectrin antibodies (data not shown). No spectrin immunoreactivity was detected in the globin, the 4.2 to 5, and the 6-globin areas.

IOV. No difference was found in the SDS-PAGE analysis of IOV obtained from thalassemia intermedia patients (spx and non-spx) and normal controls. Notably, no excess accumulation of globin was found in thalassemic IOVs (data not shown).

MS. When extracted under isotonic conditions the globin content of MS from the spx thalassemia intermedia patients was significantly higher ($11.6\% \pm 7.0\%$) than that from the non-spx thalassemia intermedia patients ($4.3\% \pm 0.7\%$) and the normal controls ($2.8\% \pm 0.5\%$) ($P < .001$) (Table 2, Fig 2). The benzidine reaction revealed

that approximately 75% ($8.8\% \pm 1.8\%$) of the globin attached to the spx thalassemic MS contained heme.

The large amount of globin in spx thalassemic MS was unanticipated, and it was therefore important to determine whether the globin was associated with the cytosol face of protein 3.²⁶ The isotonic Triton extraction leaves considerable protein 3 attached to the membrane skeleton.¹³ Therefore, RBC MS were prepared in Triton in the presence of hypertonic KCl buffer, thus producing MS containing substantially less protein 3.¹³ The increased removal of protein 3, however, was not followed by any decrease in the globin content of the thalassemia intermedia MS, which was again elevated, particularly in the spx thalassemics' MS, rising to $14.0\% \pm 5\%$ and to $7.2\% \pm 2.1\%$ in the non-spx thalassemic MS.

The globin could be firmly bound to the MS, or aggregates of cytosolic or membrane globin could have been nonspecifically enmeshed or trapped during the formation of Triton membrane skeletons. To test these possibilities MS from spx thalassemics were frozen at -20°C , thawed once, and then divided into two aliquots, one of which was saved for analysis and the other subjected to 5 seconds of sonication (see Materials and Methods). Both samples were then centrifuged and the pellets analyzed by SDS-PAGE. In one of three such experiments the globin content was initially 12.2% of the membrane protein. After freezing and thawing once,

Fig 1. SDS-PAGE of RBC ghosts from three spx (lanes A, C, G) and two non-spx (B, D) thalassemia intermedia patients. Lanes E, F, and H are three normal controls. The numbers in the left-hand margin identify the protein bands.

*Globin content expressed as a percentage of the total protein (mean ± SD).

Fig 2. SDS-PAGE gels of RBC membrane skeletons extracted under hypertonic conditions. Lanes A and E are controls, B and D are spx thalassemics, and C is a non-spx thalassemic. Lane G contains normal ghosts for reference. The numbering system on the right-hand margin is the same as in Fig 1.

the globin represented 14.1% of the membrane protein, and after sonication the globin content was 13.2% of the membrane protein. The proportion of the other membrane proteins (ie, proteins 1, 2, 3, 4.1, and 5) was unchanged by either freezing and thawing or freezing, thawing, and sonication (data not shown). In performing these experiments it became apparent that under these controlled conditions the protein 3 content of thalassemic MS was increased (Fig 2). Studies were therefore extended to include five transfusion-dependent thalassemia major patients, the blood samples being obtained just prior to transfusion. The reticulocyte-rich controls were patients with hemolysis due to vasculitis (reticulocytes, 5.5%), heart transplantation (reticulocytes, 11%), chronic myeloid leukemia (reticulocytes, 6.9%), non-spx hereditary spherocytosis (reticulocytes, 15%), and diffuse histiocytic lymphoma (reticulocytes, 7.8%). The values for the protein 3 content of MS in normal controls and five reticulocyte-rich subjects are not different (Table 3). Three patients with sickle cell anemia whose reticulocyte counts ranged from 10.4% to 21.4% were also studied. The protein 3 content of their MS were comparable in each case to the

reticulocyte-rich control values (Table 3). Spx and non-spx thalassemia intermedia patients have similar values and are therefore presented together. There are no significant differences in the protein 3 content of MS prepared from thalassemia intermedia and thalassemia major patients. However, the elevation of the protein 3 content in thalassemics is significant, and the differences between controls and thalassemia intermedia patients and between controls and thalassemia major patients have *P* values of .0009 and .0015, respectively. In addition, MS from spx thalassemic patients retained small amounts of the glycophorins detected by PAS staining. Control MS were PAS-negative as previously shown by Sheetz¹³ (data not shown).

Morphological Changes

When thalassemic MS were analyzed by using both SEM and TEM, significant morphological changes were seen in MS from the spx patients as compared with the normal controls. The SEM typically showed a fine network in normal MS that was grossly distorted in all the spx thalassemic MS (Fig 3). The morphological changes consisted of a thick and coarse mesh that contained large excrescences. When analyzed by TEM (Fig 4), these bumps were seen to consist of electron-dense material that was unevenly distributed in the spx thalassemic MS and had an appearance similar to that described for Heinz bodies.

DISCUSSION

The β -thalassemic RBC provides an example wherein events inside red cells lead to the premature removal of affected RBC. We postulate that the unmatched α -globin aggregates lying at the membrane cytosolic face cause an alteration transmitted to the external membrane surface that eventuates in macrophagic attack and removal of the affected cells. The signal to the macrophage might be complex. There is known to be a decrease in thalassemic membrane sialic acid residues that is unevenly distributed.⁷ It has been recently shown that after the removal of the sialic residues there is exposure of the underlying galactosyl residues to which the naturally occurring antigalactosyl antibodies bind,³ thus providing an Fc signal to macrophages. Reduced RBC deformability has also been described in thalassemia,²⁷ and such a change could, by prolonging the contact between damaged RBC and the macrophage, result in greater opportunity for macrophagic attack. RBC rigidity in thalassemia is not caused by an increased mean corpuscular hemoglobin concentration or by a reduced surface area-to-volume ratio but is most likely caused by an altered membrane modulus.²⁸ This change in membrane function could also be caused by the accumulation of α -globin aggregates at the membrane cytosol face that affect either integral membrane or MS proteins or both.

In this study as in prior studies,^{29,30} SDS-PAGE analysis of RBC ghosts from spx thalassemic patients revealed an increase in their globin content as compared with the non-spx patients and normal controls (Table 1, Fig 1). In addition, extra polypeptides in the protein 4.2 to 5 and 6-globin areas appeared in the ghosts from the spx thalassemia intermedia RBC and were free of spectrin degradation products as

Table 3. Protein 3 Content of MS Prepared in the Presence of Hypertonic KCl

	Protein 3 (%)
Normal subjects (8)	12.6 $\pm$ 1.8
Reticulocyte-rich patients (5)	9.9 $\pm$ 2.2
β -Thalassemia intermedia (4 spx, 3 nonspx)	16.6 $\pm$ 1.8
β -Thalassemia major (5)	17.9 $\pm$ 2.7
SS-1	8.6
SS-2	9.9
SS-3	7.2

NOTE. Values are calculated as a percentage of the total membrane protein less the globin and protein 6-globin content (mean $\pm$ SD). The numbers in parentheses are the number of subjects studied.

Fig 3. Scanning electron micrograph of RBC membrane skeleton from a normal control (A) and a spx thalassemic patient (B). (Original magnification $\times 6,000$.)

detectable by the Western immunoblot technique. The appearance of these extra polypeptides occurred despite the regular use of comprehensive antiproteolysis measures. These polypeptides could result from attachment of cytoplasmic proteins such as catalase to the thalassemic membranes.

Alternatively some of these bands could represent dimers, trimers, or even tetramers of native or degraded hemoglobin. Allen and Cadman³¹ have shown in an in vitro model that an increase in calcium uptake by RBC induces similar changes in their membrane polypeptides. We have recently demonstrated that there is an increased calcium content in β -thalassemia intermedia RBC that was most pronounced in the spx patients.³² It is therefore possible that calcium plays an important role in thalassemic RBC that is apparent despite the rigorous antiproteolysis measures taken. We compared the changes in spx thalassemic ghosts with the ghosts from patients with other hemoglobinopathies. The increase in polypeptides in the 4.2 to 5 and 6-globin areas seems to be nonspecific. However, the elevation in globin content in the spx thalassemic is considerably greater than the values seen in three patients with sickle cell anemia who are thought to be hyposplenic by conventional clinical criteria.

Resolution of membranes into their integral proteins (ie, IOV) and MS components revealed that there were no differences in IOV from thalassemia intermedia patients (spx or non-spx) and controls. The absence of globin from IOVs prepared from spx thalassemia intermedia patients suggested either that the globin was not attached to integral

proteins or lipids or that it could be removed by low-ionic strength media. Surprisingly it was the MS from the spx thalassemia intermedia patients that contained significantly increased amounts of globin at a level that was approached by only one of the three sickle cell anemia patients studied (Table 2). This globin could not be removed by fairly drastic physical means consisting of freezing and thawing with or without subsequent sonication. The proportion of other membrane proteins, particularly protein 3, was also not altered by these treatments. Therefore it is likely that the globin and other perhaps associated membrane constituents are firmly bound to membrane skeletons. Protein 3 is known to be one of the membrane binding sites for hemoglobin²⁶ and for hemichromes.³³ Therefore we used hypertonic KCl to increase the Triton extraction of protein 3 from thalassemic MS. However, this maneuver was not followed by any decrease in globin content (Table 2). Thus it is possible that cytoskeletal proteins serve as an attachment site for globin aggregates. Snyder et al³⁴ reported that during in vivo senescence there is increased binding of globin chains to spectrin, and it has been hypothesized that it is the α -chain of hemoglobin that binds to the α -chain of spectrin.³⁵ However, our data do not identify the site(s) of attachment of the putative α -globin aggregates to the membrane skeleton. The idea that association of globin aggregates to MS components occurs in spx thalassemics is further supported by the distinctly abnormal morphology of the MS from spx thalassemics. On SEM the MS from spx thalassemic intermedia patients displayed coarse stranding and bumps (Fig 3), and on conventional TEM, the bumps were aggregates of unevenly scattered electron-dense material. The possibility that these inclusion bodies, originally thought to be Heinz bodies, represent α -globin aggregates is intriguing but remains to be proved.

In the course of performing experiments using hypertonic KCl to strip off more protein 3 from MS we observed that the level of protein 3 was increased in MS prepared from severe β -thalassemia patients (Table 3, Fig 2) but not in another hemoglobinopathy, sickle cell anemia. This increase in protein 3 was evident in both spx and non-spx thalassemia intermedia patients as well as transfusion dependent thalassemia major patients whose RBC are a mixed population. The lack of correlation between globin content and protein 3 content of the MS indicates that these are probably unrelated phenomena and that globin aggregates do not serve to link most of the protein 3 to the MS. Attachment of an

Fig 4. Transmission electron micrograph of RBC membrane skeleton from a spx thalassemic patient. (Original magnification $\times 24,500$.)

integral protein like protein 3 to the cytoskeleton could result in an increase in membrane rigidity. Chasis et al³⁶ have shown that the increased RBC rigidity produced by monoclonal antiglycophorin A antibody is associated with the attachment of glycophorin A to the MS. In fact, MS prepared from splenectomized β -thalassemic patients retain some glycophorin as indicated by PAS staining. Recent data suggest that β -thalassemic protein 4.1 has abnormal structure and function.³⁷ The retention of integral membrane proteins on the thalassemic skeleton might therefore be a consequence of abnormal interaction of protein 4.1 with both protein 3³⁸ and some of the glycophorins.³⁹

These studies are the first to explore the MS and IOVs of severely affected patients with β -thalassemia and show abnormalities in membrane skeletal assembly of their RBC. One of these changes, the increase in globin association to

MS, is most clearly seen in spx thalassemic patients, thereby suggesting that this change may define in part the most severely affected cohort of cells that are preferentially removed by the splenic macrophages. However, the increase in protein 3 and glycophorins in MS is a common finding in all severe β -thalassemic MS studied and may represent a mechanism that could serve to produce RBC rigidity. These abnormalities may be a consequence of the hemichrome-mediated oxidative potential described in thalassemics.⁴⁰ Further experiments will be needed to test these and other hypotheses.

ACKNOWLEDGMENT

Development of the Human Coagulation System in the Full-Term Infant

By Maureen Andrew, Bosco Paes, Ruth Milner, Marilyn Johnston, Lesley Mitchell,
Douglas M. Tollefsen, and Peter Powers

The investigation of many hemostatic defects in the newborn is limited by the lack of normal reference values. This study was designed to determine the postnatal development of the human coagulation system in the healthy full-term infant. Consecutive mothers of healthy full-term infants born at St Joseph's Hospital in the city of Hamilton were approached for consent. One hundred eighteen full-term infants (37 to 42 weeks' gestational age) were entered into the study. Demographic information and a 2-mL blood sample were obtained in the postnatal period on days 1, 5, 30, 90, and 180. Between 40 and 79 full-term infants were studied on each day for each of the coagulation tests. Plasma was fractionated and stored at -70°C for batch assaying of the following tests: prothrombin time, activated partial thromboplastin time, thrombin clotting time, and factor assays (biologic): fibrinogen, II, V, VII, VIII, IX, X, XI, XII, and high-molecular weight kininogen. Factor

XIII subunits A and S, von Willebrand factor, and the inhibitors antithrombin III, α_2 -antiplasmin, α_2 -macroglobulin, α_1 -antitrypsin, C1 esterase inhibitor, protein C, and protein S were measured immunologically. Plasminogen, prekallikrein, and heparin cofactor II were measured by using chromogenic substrates. The large number of infants studied at each time point allowed us to determine the following: (a) the range of normal for each test at five time points in the postnatal period; (b) that coagulation tests vary with the postnatal age of the infant; (c) that different coagulation factors show different postnatal patterns of maturation; and (d) that near-adult values are achieved for most components by 6 months of life. In summary, this large cohort of infants studied consecutively in the postnatal period allowed us to determine the normal development of the human coagulation system in the full-term infant.

© 1987 by Grune & Stratton, Inc.

THE HEMOSTATIC SYSTEM in the neonate has many unique features when compared with the adult. In general, the screening tests are prolonged at birth, the coagulation factor levels are low, and both are dependent on the gestational and postnatal age of the infant. There are published reference values for healthy infants for most coagulation factors at the time of birth; however, these data are based primarily on cord blood samples and not on samples from the infant.¹⁻¹⁶ There is minimal or no data for some components of the coagulation system during the first week of life and scarce information beyond that time. Most of the studies reporting normal values for coagulation factors in the postnatal period have used small sample sizes that allow a determination of the mean value but not an accurate assessment of the variability of the values. Thus, to date there are no reference values that allow one to determine with any degree of confidence whether a particular infant who presents with a bleeding problem has normal or abnormal values. The purpose of the following study was to determine for full-term infants the normal values for the majority of known coagulation factors and coagulation inhibitors during the first 6 months of life.

MATERIALS AND METHODS

Subjects. Healthy full-term infants (≥ 37 weeks' gestational age) born at St Joseph's Hospital in Hamilton between December 1, 1983, and March 1, 1984, were eligible for this study. Gestational age was determined based on maternal dates and the Dubowitz assessment. These infants did not experience any perinatal problems, and all received 1 mg of vitamin K intramuscularly at the time of birth, at least 12 hours prior to the first blood sample being drawn. Information regarding head circumference, crown-heel length, weight, milk formula, and medications was recorded at each visit. Informed consent was obtained from the parents of all infants, and the study was approved by the St Joseph's Hospital Ethics Review Committee. In addition, 29 healthy adults receiving no medications were studied with the same laboratory methods as the infants.

Laboratory. Blood samples (2 mL) were usually obtained from a dorsal hand vein by using a 1½-in 21-gauge straight needle with the hub removed. The blood flowed directly into a premarked plastic tube containing 3.2% buffered sodium citrate (one part citrate to

nine parts blood). The samples were collected in the postnatal period on days 1, 5, 30, 90, and 180. The anticoagulant-to-blood ratio was not altered for the venous hematocrit because this value was not available. However, based on hematocrit values in the healthy newborn from our institution, 95% of the infants would have had an acceptable anticoagulant-to-blood-ratio.

The blood was immediately centrifuged (1,700 g) and platelet-poor plasma removed and frozen for future coagulation studies. Each 2 mL of blood gave a minimum of 600 μL of plasma, and all assays were performed by using previously published microtechniques.¹⁷ The coagulation screening tests, consisting of a prothrombin time (PT) (Dade C rabbit thromboplastin), activated partial thromboplastin time (APTT) (Dade FS), and 2-unit thrombin clotting time (TCT), used 20 μL each. Fibrinogen was measured as a thrombin clottable protein using 10 μL of plasma.¹⁸

The following coagulation factor assays were performed with human deficient plasma and 10 to 30 μL of each infant's plasma. Factors VIII-, IX-, XI-, and XII-deficient plasmas were obtained in-house from known severely deficient patients (<0.01 U/mL). High-molecular weight kininogen (HMW-K)- and prekallikrein (PK)-deficient plasmas were obtained from George King Biomedical, Overland Park, KS and factor VII-deficient plasma was

prepared by immunodepletion of normal plasma (Interhaematol, Burlington, Ontario). Factor V-deficient plasma was prepared in-house by prolonged incubation of normal plasma collected into sodium oxalate. Factor II-deficient plasma was prepared from bovine plasma by adsorption with tricalcium phosphate. Factor X-deficient plasma was purchased from Sigma Chemical Co, St Louis, as VII-, X-, and bovine-deficient plasma. Factor XIII, subunits A and S, was measured by using Laurel immunoelectrophoresis. The antibodies were obtained commercially from Behring (Hoescht, Montreal). The plasma protease inhibitors antithrombin III (AT-III), α_2 -antiplasmin (α_2 -AP), C1 esterase inhibitor (C1E-INH), α_2 -macroglobulin (α_2 -M), and α_1 -antitrypsin (α_1 -AT) were all measured immunologically with commercially available rabbit antihuman antibody (Atlantic Antibodies, NCS Diagnostics, Inc, Mississauga, Ontario) by using a radial immunodiffusion that required 3 to 5 μ L per assay. Heparin cofactor II (HCII) was measured biologically on 50 μ L of plasma by a previously published method.¹⁹ Protein C was measured by an enzyme-linked immunosorbent assay (ELISA) (Diagnostica Stago, Wellmark Diagnostics, Guelph, Ontario). von Willebrand factor (vWF) was also measured by an ELISA method.²⁰ Protein S (Interhaematol) was measured by quantitative immunoelectrophoresis using rabbit antihuman protein S antibody.²¹ PK and plasminogen were each measured biologically on 10 to 20 μ L of plasma by chromogenic assays.^{22,23}

The sample size calculation was based on previously published

data. The α and β errors were set at 0.05 and 0.1, one-tailed, respectively. The change in time over the postnatal period for each factor level was measured by a one-way analysis of variance. The newborn values at each time were compared with the adult values to determine when they were statistically indistinguishable by using Dunnett's test. All *P* values < .05 were considered significant.

RESULTS

Subjects. Of 359 mothers interviewed, 118 agreed to have their infants join the study. Of these 118 mothers, 93 agreed to return for follow-up appointments. Between 61 and 77 infants returned and were studied at each time point for each assay. Not all infants were studied at each time point, primarily because of failure to return for follow-up, recruitment after day 1 of life, discharge before day 5, and occasionally clotted samples. The infant population was white (98%), with an equal proportion of males (53%) and females (47%). The mode of delivery was vaginal (98%), and all infants had a five-minute Apgar score ≥ 7 . The mean values for the weight, head circumference, and length of the infants in our study population at each time point are given in Table 1 as well as the proportion who were breast-fed at each time point.

NOTE. All factors except fibrinogen and plasminogen are expressed as units per milliliter where pooled plasma contains 1.0 U/mL. Plasminogen units are those recommended by the Committee on Thrombolytic Agents (CTA). All values are expressed as mean ± 1 SD.

Abbreviation: VIII, factor VIII procoagulant.

*Values that do not differ statistically from the adult values.

†These measurements are skewed because of a disproportionate number of high values. The lower limit that excludes the lower 2.5th percentile of the population has been given in the respective figures. The lower limit for factor VIII was 0.50 U/mL at all time points for the infant.

Laboratory. Tables 2 and 3 give the mean ± 1 SD and the number of samples tested for the coagulation factors and inhibitors, respectively. Figures 1 to 7 give the mean values $\pm 95\%$ confidence intervals for the mean value and the upper and lower limits that encompass 95% of the population (± 2 SD) for each of the tests performed. The 95% confidence interval for the mean value of each test at each time point was very small (less than $\pm 0.06\%$) in the coagulation tests in this population, which allowed us to accurately detect changes over time. Values that were skewed were identified in Tables 2 and 3 and the lower limit adjusted to exclude 2.5% of the population. The values that do not differ significantly from those of the adult are identified in Tables 2 and 3.

Table 2 and Fig 1 give the values for the coagulation screening tests in the first 6 months of life. The PT significantly shortened during the first month of life but was always comparable to the adult value. The APTT, which was prolonged at birth, reached adult values by 3 months of age. The TCT was in the adult range from time of birth, as was the fibrinogen level; however, there was a significant rise in the fibrinogen level on day 5 of life.

Table 2 and Fig 2 give the values for the vitamin K-dependent factors (II, VII, IX, and X) in the first 6 months of life. Each of the vitamin K-dependent factors had a distinct postnatal pattern of maturation. Levels of factor VII rapidly rose to near adult levels by day 5 of life, which contributed to the shortening of the PT at this same postnatal time point. Levels of factors II, IX, and X showed a relatively delayed rise. All four vitamin K-dependent factors were in the adult range at 6 months of life; however, the mean values for all four factors were still significantly lower in the infant compared with the adult. There was no difference between breast-fed and formula-fed infants for any of the vitamin K-dependent factors at any time point.

Table 2 and Fig 3 give the values for the four contact factors (XII, XI, PK, and HMW-K) during the first 6 months of life. The levels of these factors were all low at the time of birth. Levels of HMW-K rapidly rose to adult values by 1 month of life, whereas levels of factors XI, XII, and PK showed a gradual rise into the adult range by 6 months of age. The mean values for factors XI, XII, and PK were still significantly lower in the infant compared with the adult at 6 months of age.

Table 2 and Figs 4 and 5 give the postnatal course for factors V, VIII, vWF, plasminogen, and factor XIII with its subcomponents A and B. The mean value for factor V was in the adult range at birth and rose to 0.95 U/mL by day 5 of

Fig 1. APTT, PT, fibrinogen level, and TCT in 118 healthy full-term infants throughout the first 6 months of life. The inner line represents the mean values, the inner clear area the 95% confidence interval, and the shaded area 95% of all values (± 2 SD).

Adult values are indicated

life. Factor VIII and vWF showed a persistently skewed distribution with a number of very elevated values. The lower limit of normal has been adjusted to reflect the true limit excluding 2.5% of the population. The mean value for factor VIII at birth was the same as the adult, whereas levels of vWF were elevated compared with the adult. Levels for both factors VIII and vWF gradually decreased over the first 6 months of life. For factor VIII, only three values out of 306 tests were below 0.40 U/mL, and these three values were all above 0.30 U/mL. Factors XIIIa and XIIIb showed essentially identical patterns with indistinguishable mean values. Adult levels for both factors XIIIa and XIIIb were achieved by day 5 of life. Plasminogen values were approximately two thirds of adult values at birth and gradually rose to near-adult values by 6 months.

Table 3 and Fig 6 give the postnatal course for the inhibitors AT-III, HCII, protein C, and protein S. All of these inhibitors had low levels at the time of birth. The mean values for AT-III were similar for the infant and adult by 3 months of age, whereas the mean value for HCII was high in the infant at 6 months of age compared with the adult. Protein C still had markedly low levels at 6 months of age.

Table 3 and Fig 7 give the values for the inhibitors, α_2 -M,

Table 3. Reference Values for the Inhibition of Coagulation in the Healthy Full-term Infant During the First 6 Months of Life

Inhibitors	Day 1 (n)	Day 5 (n)	Day 30 (n)	Day 90 (n)	Day 180 (n)	Adult (n)

Adult values are indicated

Fig 4. Factors V, VIII, and vWF in 118 healthy full-term infants throughout the first 6 months of life. The inner line represents the mean values, the inner clear area the 95% confidence interval, and the shaded area 95% of all values (± 2 SD). Adult values are indicated

C₁E-INH, α_2 -AP and α_1 -AT. Levels for α_2 -M were elevated at birth compared with the adult, and these values continued to rise in the postnatal period. Although levels for C₁E-INH were low at birth compared with the adult, the levels for C₁E-INH also continued to rise well above adult values during the first 6 months of life. In contrast, levels of α_2 -AP at birth were in the lower part of the adult range and achieved the adult values by day 5 of life. The levels of α_2 -AP then remained constant over the first 6 months of life. Levels of α_1 -AT were similar in the neonate compared with the adult; however, the levels of α_1 -AT in the neonate fell by 3 months of age and by 6 months of age had begun to increase again.

DISCUSSION

A knowledge of the normal postnatal development of the human coagulation system is essential to investigate thrombotic and hemorrhagic problems in the neonate. The definition of normal values of any one parameter in a single population is a difficult task. Physicians caring for infants

Fig 5. Factor XIIIa, XIIIb, and plasminogen in 118 healthy full-term infants throughout the first 6 months of life. The inner line represents the mean values, the inner clear area the 95% confidence interval, and the shaded area 95% of all values (± 2 SD). Adult values are indicated

with hemostatic problems are faced with a need to establish normal values for at least 25 coagulation parameters that are known to be constantly changing over the first few weeks to months of life. To complicate matters further, these changing parameters are not only dependent upon the postnatal age of the infant but are also dependent upon the gestational age. The problem is further compounded by the difficulty of obtaining adequate blood samples, the small size of the sample that can be taken, the necessity of using microtechniques to perform the multiple assays on small samples, and the large number of infants who must be studied because of the greater variability that exists at any single time point for any coagulation measurement in the neonatal population compared with the adult. Because of these difficulties, the normal postnatal development of the human coagulation system in the full-term infant is still largely unknown. Our study was designed to determine the normal postnatal values for the components of the coagulation, fibrinolytic, and inhibitor systems in the healthy full-term infant.

The PT, APTT, TCT, and fibrinogen levels are the most

Fig 6. The inhibitors AT-III, HCII, protein C, and protein S in 118 healthy full-term infants throughout the first 6 months of life. The inner line represents the mean values, the inner clear area the 95% confidence interval, and the shaded area 95% of all values (± 2 SD). Adult values are indicated

commonly used screening tests in infants with a suspected coagulopathy. There are reference mean values published for these tests in the first week of life¹⁻¹⁶; however, this study has extended our information for these tests in a number of ways. Previously the mean PT values have been reported to be prolonged at birth and to reach adult values by a week of life. This study showed that although the variability of the PT was greater in the newborn, the mean values were not significantly different from the adult. The PT did shorten in the newborn during the first month of life. Previously reported values for the APTT in the neonate were so prolonged that the usefulness of the APTT as a diagnostic test in the infant was questionable.^{1,4} By using a reagent containing ellagic acid rather than kaolin as an activating agent we were able to considerably narrow the ranges of normal, which may increase the usefulness of the APTT as a screening test in the neonate. In the neonate, the TCT can be of limited value when performed without calcium in the buffering system because under these conditions the TCT may be prolonged due to a normally present fetal fibrinogen.²⁴ In this study, the TCT was measured with calcium present in the buffering system so that a narrow normal range was delineated and abnormal values secondary to the presence of heparin or low levels of fibrinogen could be easily detected. Previously, an elevated fibrinogen level has been used as an indicator of sepsis in the neonate.^{25,26} The normally elevated levels of fibrinogen on day 5 of life suggests that this is at least in part a physiological postnatal phenomenon and may not be indicative of sepsis.

The levels of the four vitamin K-dependent factors have been extensively studied in the full-term infant.²⁷⁻³² Vitamin

Fig 7. The inhibitors C₁E-INH, α_2 -M, α_2 -AP, and α_1 -AT in 118 healthy full-term infants throughout the first 6 months of life. K deficiency can occur in the full-term neonate although the true incidence and frequency of bleeding manifestations is unclear.³³ All of our infants received vitamin K at birth, so our reference values may apply only to other infants who have received vitamin K at the time of birth. Vitamin K deficiency has also been reported to occur later in the postnatal period in infants who have received vitamin K at birth and are breast-fed.²⁹ Our sample size was too small to determine with accuracy the frequency of vitamin K deficiency at 1 month in infants who received vitamin K at birth. However, we subanalyzed our data to compare breast-fed and formula-fed infants for all of the vitamin K-dependent factors at each time point, and there was no significant difference detected, which is compatible with previously reported data at 1 month of age.²⁹ Finally, our data showed that the severe form of Christmas disease or factor IX deficiency can be diagnosed at the time of birth; however, moderate and mild forms are likely not reliably diagnosed.

The levels for the four contact factors (XII, XI, PK, HWM-K) were low at birth and gradually increased to values approaching the adult values by 6 months of life. The low levels of these four factors likely contribute to the prolonged APTT during the first 6 months of life.^{4,34-39} The

homozygous form of factor XI can be reliably detected as early as day 5 of life because the lower limit of our range at this time was 0.20 U/mL, which is above the levels for homozygous factor XI-deficient patients.

The factor VIII molecule has been extensively studied in the immediate postnatal period.⁴⁰⁻⁴⁷ Our study showed similar results; however, the values for factor VIII were skewed, with many infants having elevated values at the time of birth. Less than 1% of the values for factor VIII were below 0.40 U/mL, and all values were above 0.30 U/mL. Thus, severe and moderate hemophilia A can be reliably diagnosed in the immediate postnatal period. vWF levels have been reported to be elevated in healthy full-term infants, and our data would be compatible with the published results.^{40,42-45,47} In addition, our study showed that vWF levels remain elevated until 3 months of age, thus suggesting that the elevated levels were not a brief response to the birth process itself.

Some of the inhibitors of the coagulation system have been studied in part.⁴⁸⁻⁵⁸ In our study, levels of C₁E-INH, α_2 -M, and HCII became elevated during the first 6 months of life compared with the adult. The significance of these elevated values is unknown, but one may speculate that this may be in part compensation for the low levels of other inhibitors. Levels of AT-III, protein C, protein S, and HCII were low in the first weeks of life and all in the range in which thrombotic disorders have been described in the adult. Of some interest, protein C still had markedly depressed levels at 6 months of age. All of the inhibitors in our study except for HCII were measured by immunologic assays. Whether any of these proteins have lower biologic activity compared with immunologic levels has been questioned by other investigators but was not addressed in this particular study.^{49,58}

In summary, our study has determined the postnatal development of the human coagulation system in a large number of consecutively studied healthy full-term infants. Utilizing these reference values, future studies will be directed at the determination of the epidemiology and clinical impact of specific abnormalities and the role of therapeutic interventions in specific hemorrhagic and thrombotic problems in the neonate.

ACKNOWLEDGMENT

The authors would like to acknowledge the secretarial assistance of R. Phillis, B. Lahie, and J. Butera. In addition, we would like to acknowledge the organizational skills of A. Lang and B. Stewart-Rudolf and the technical support provided by the technologists at the Coagulation Laboratories at St Joseph's Hospital and at McMaster University Medical Centre. In addition, we would like to thank the technologist A. Verges for her assistance and the nursery staff at St Joseph's Hospital for their invaluable support in the collection of blood samples.

Proteolytic Degradation of von Willebrand Factor After DDAVP Administration in Normal Individuals

By Javier Batlle, Maria Fernanda Lopez-Fernandez, A. Lopez-Borrascas, Consuelo Lopez-Berges, Judith A. Dent, Scott D. Berkowitz, Zaverio M. Ruggeri, and Theodore S. Zimmerman

The infusion of 1-deamino-8-D-arginine vasopressin (DDAVP) in normal individuals is followed by an increase in factor VIII/von Willebrand factor (vWF) in plasma, by an increase in intensity of all sizes of multimers, and by the appearance of larger multimers of vWF than those seen in the resting state. Since the larger multimers are rapidly cleared and proteolysis is known to cause disaggregation of large multimers, we evaluated the degree of vWF proteolysis after DDAVP administration. DDAVP was infused into eight normal adult volunteers, and the relative proportions of the intact 225 kilodalton (kDa) subunit and the 189, 176, and 140 kDa vWF fragments were compared before and at different times after DDAVP infusion. The

relative proportion of the 176 kDa fragment was increased, whereas that of the other species was decreased, thereby indicating that proteolytic fragmentation had occurred. However, plasmin did not appear to be responsible because the vWF fragments characteristically produced by this enzyme could not be detected. Concomitant analysis of vWF multimeric structure showed that these changes were accompanied by an increase in the relative proportion of the satellite bands, which suggests that they were proteolytically generated. Proteolysis may explain, at least in part, rapid clearance of larger vWF multimers released by DDAVP.

© 1987 by Grune & Stratton, Inc.

RECENTLY it has been demonstrated that a small but consistent proportion of the von Willebrand factor (vWF) in normal plasma is composed of fragments with apparent molecular masses of 189, 176, and 140 kilodaltons (kDa) that have been cleaved from the 225 kDa subunit, indicating that proteolysis normally plays a role in the processing of vWF.¹

The infusion of 1-deamino-8-D-arginine vasopressin (DDAVP) in normal individuals is followed by an increase in vWF levels, by an increase in the intensity of all sizes of multimers, and by the appearance of multimers that are larger than those seen in the resting state and that are progressively cleared.² Also, DDAVP releases plasminogen activator.^{3,4}

To better understand the processing of this DDAVP-released vWF we have studied the vWF multimeric and subunit composition in normal individuals at baseline and after DDAVP infusion. We have found that at least to some extent DDAVP infusion is accompanied by the induction of proteolytic degradation of vWF. Monoclonal antibody mapping of the fragments indicated that plasmin was not responsible. Thus, the increased fragmentation could not have resulted from plasminogen activation subsequent to plasminogen activator release by DDAVP. However, the enzyme or enzymes responsible are unknown at present.

Previous studies have provided evidence that the vWF molecule in IIA von Willebrand's disease (vWD) is more susceptible to cleavage than normal vWF.^{1,5} The results presented here suggest that the failure of DDAVP to control bleeding in some individuals with IIA vWD may result from an unfavorable balance between release of large multimers and their proteolytic degradation.

MATERIALS AND METHODS

Reagents. Leupeptin and *N*-ethylmaleimide (NEM) were acquired from Sigma Chemical Co, St Louis; electrophoresis pure reagents from Bio-Rad, Richmond, CA; and rabbit antimouse IgG was from Zymed, South San Francisco. All other reagents were of the highest grade available.

Patients. Eight normal volunteers, five males and three females aged between 18 and 36 years with no drug intake for at least 20 days before the study, were included. DDAVP (Minirin, Ferring

Laboratories, Malmo, Sweden) at a dose of 0.4 µg/kg body weight was diluted with 100 mL of normal saline and infused intravenously over a 30-minute period. vWF antigen (vWF:Ag) and ristocetin cofactor activity were determined as described.⁶ Blood was drawn before (0) and after (30 and 60 minutes and 2, 4, and 24 hours, respectively) DDAVP administration. Plasma samples were obtained in the presence of 1 mmol/L leupeptin, 6 mmol/L NEM, and 5 mmol/L EDTA as described.⁶

Immunoisolation of vWF. vWF was immunisolated by incubation of 1 to 5 mL of plasma with 1 to 2.5 mL of agarose beads covalently linked to anti-vWF monoclonal antibody as described.¹ After extensive washing the vWF was eluted with 2 mL of 2% sodium dodecyl sulfate (SDS) and 0.1 mol/L Tris (pH 8.0) at 60°C, and the eluate was concentrated by using Amicon Centricron 30 microconcentrators (Amicon Corp, Danvers, MA) to a final volume of approximately 100 µL.¹

SDS-polyacrylamide gel electrophoresis and immunoblotting. SDS-5% polyacrylamide gels were prepared according to Laemmli.⁷ The vWF was reduced by dithiothreitol (final concentration, 65 mmol/L) for 15 minutes at 60°C in pH 7.0 polyacrylamide gel sample buffer. After SDS-5% polyacrylamide electrophoresis the samples were electrophoretically transferred to nitrocellulose

and then reacted with a pool of 55 anti-vWF monoclonal antibodies, all of which reacted with the reduced 225 kDa subunit.¹ The nitrocellulose was then reacted with ¹²⁵I-rabbit antimouse IgG antibody. The relative concentrations of the intact vWF subunit and its proteolytic fragments were determined by identifying each band by autoradiography and then excising each band and counting them in a γ -scintillation counter (Clinigamma, LKB, Bromma, Sweden).

Immunoblots were also made with monoclonal antibody pools that reacted only with an amino-terminal cyanogen bromide fragment (M7) or a carboxy-terminal cyanogen bromide fragment (M31) and that differentiated between the "native" 176 and 140 kDa fragments and the plasmin-cleaved fragments of similar size.⁸

SDS-agarose electrophoresis. For analysis of vWF multimers this procedure was performed as described.⁹ In brief, thin-layer agarose electrophoresis was performed in the presence of SDS by using a discontinuous buffer system. vWF multimers were identified autoradiographically by reacting the gels with [¹²⁵I]-labeled affinity purified anti-vWF rabbit antibody.¹⁰

Statistical analyses. To analyze the evolution of the proteolytic fragments of vWF induced by the infusion of DDAVP, we first studied the mean percentage of counts per minute of each polypeptide at six different times (0, 30, and 60 minutes and 2, 4, and 24 hours) in the eight individuals. We corroborated the normality of the distributions by using the STAWORKS program. The mean values of each band at different times were then compared with each other by both a parametric test (Student's *t* test) and a nonparametric test (Wilcoxon signed rank), and the *P* value was calculated. As a consequence of the need to make multiple comparisons of variable pairs, which can artifactually increase the level of statistical significance, we calculated the maximum probability of error admissible by using the Bonferroni method, a procedure that determines the acceptable maximal error to be admitted. In that regard a maximal error of 5% was admitted. In addition, we have analyzed the evolution of each band in comparison with the others by using the Spearman correlation test to determine whether they are dependent on or independent of each other's evolution.¹¹

RESULTS

DDAVP infusion produced a concomitant increase in vWF:Ag and ristocetin cofactor activity to about two or three times the resting concentration, being maximal at 30 to 120 minutes, as already described.² All multimers of vWF showed an increase in plasma concentration, and larger multimers than those initially present in plasma also appeared and reached a maximum at 30 minutes (Fig 1). The larger multimers disappeared from the circulation by two to four hours. With higher-resolution gels, an increase in the relative proportion of the satellite bands, as compared with the predominant central band, of each repeating multimeric unit was observed. This alteration was maximal approximately 60 minutes after the infusion and was almost entirely gone by 24 hours (Fig 2).

Immunoblots made with the pool of 55 anti-vWF monoclonal antibodies showed a significant increase in the relative concentration of the 176 kDa fragment in comparison with that of the intact 225 kDa subunit and the 189 and 140 kDa fragments. This change was already present at 30 minutes (*P* < .006) and became maximal at two hours after the infusion (Figs 3 and 4). At 24 hours the subunit pattern was similar to that observed in the resting state.

To evaluate the possibility that the increase in the 176 kDa fragment represented an increase in the species normally

Multimers of vWF larger than those seen in the basal state appear by 30 minutes after the infusion, with a progressive disappearance and a return to the resting pattern at 24 hours. The arrow marks the interface between the stacking (sample) and running gels.

present in plasma or resulted from plasmin cleavage consequent to the release of plasminogen activator by DDAVP, monoclonal antibody mapping studies were performed. A pool of monoclonal antibodies reactive with a cyanogen bromide fragment derived from the amino-terminal portion

Fig 2. Autoradiograph of SDS-1.6% agarose gel electrophoresis of normal plasma at the same times as in Fig 1. A transient increase in the relative proportion of the satellite bands, as compared with the central predominant band, of the smallest two multimers (brackets) became evident after DDAVP administration. The arrow marks the interface between the stacking (sample) and running gels.

Fig 3. Immunoblot autoradiograph of reduced immunoprecipitated vWF before (0) and after (30 and 60 minutes and 2, 4, and 24 hours, respectively) the infusion of DDAVP. vWF was reacted with a pool of 55 anti-vWF monoclonal antibodies. An increase of the 176 kDa fragment relative to that of the 225, 189, and 140 kDa species was evident after DDAVP administration; recovery occurred by 24 hours. A band migrating more slowly than the 225 kDa subunit is partially reduced vWF (white arrow). The exposure time of this autoradiograph was too short to allow good visualization of the 140 kDa fragment. The black arrow marks the interface between the stacking (sample) and running gels.

of the 2,050-amino acid residue vWF subunit (M7, residues 185 to 288)¹² and a pool of monoclonal antibodies reactive with a cyanogen bromide fragment from the carboxy-terminal portion of the subunit (M31, residues 1,481 to 1,693)¹² were used in the immunoblots in place of the 55-antibody pool.

The M7 antibodies react with the 140 kDa fragment present in normal plasma in the resting state, which is therefore derived from the amino-terminal portion of the molecule, and with a 176 kDa plasmin-derived amino-terminal fragment.⁸ This pool of antibodies reacted only with the 140 kDa species in the post-DDAVP specimens, thereby indicating that the increased quantity of the 176 kDa species

Fig 4. Relative proportion of counts in each of the bands shown in Fig 3 as determined by excising each band from nitrocellulose and measuring γ -scintillation counts (mean percentage of total counts per minute of each polypeptide). Brackets indicate ± 1 SD. An increase in the 176 kDa polypeptide relative to the other species was evident after DDAVP administration; return to normal occurred by 24 hours. $\square$, 225 kDa; $\blacksquare$, 189 kDa; $\square$, 176 kDa; $\blacksquare$, 140 kDa.

was not attributable to a plasmin-cleaved product of this size (Fig 5).

The M31 antibodies, on the other hand, react with the 176 kDa fragment present in normal plasma in the resting state, which is therefore carboxy-terminal in its derivation, and with a 145 kDa carboxy-terminal plasmin cleavage product.⁸ These antibodies detected only a native 176-kDa species in the post-DDAVP specimens, again providing evidence that plasmin cleavage of vWF had not occurred (not shown).

DISCUSSION

In vivo proteolysis of vWF has recently been demonstrated in normal individuals by showing that a small but consistent proportion of the vWF 225 kDa subunit is present in normal plasma as cleaved fragments with apparent molecular masses of 189, 176, and 140 kDa.¹ In type IIA vWD the relative proportion of the 176 and 140 kDa fragments is increased, which supports the hypothesis that proteolysis is responsible, at least in part, for the absence of large multimers in that disorder.^{1,5,6} Plasmin, the platelet calcium-activated protease (calpain), and one or more enzymes released from polymorphonuclear leukocytes proteolyze vWF in vitro, with resultant loss of large multimers.^{6,13-16} However, it is not clear whether any of these enzymes has a similar effect in vivo.

By using monoclonal antibodies to map the fragments to different portions of the vWF subunit it was previously

Fig 5. Immunoblot autoradiograph of reduced immunoprecipitated vWF reacted with M7 monoclonal antibodies. Left panel: normal plasma vWF before (0) and after (60 minutes and two hours, respectively) DDAVP administration and drawn in the presence of 1 mmol/L leupeptin, 6 mmol/L NEM, and 5 mmol/L EDTA. Right panel: vWF from normal untreated plasma (-UK) and vWF from plasma reacted with urokinase (+UK). Normal untreated plasma was drawn in citrate anticoagulant with the three proteinase inhibitors as before. Plasma to be reacted with urokinase (384 Ploug U/mL of plasma) was drawn in citrate anticoagulant alone and incubated with the enzyme at 37°C for 16 hours.⁸ The 176 kDa amino-terminal fragment produced by plasmin is present in the in vitro urokinase-treated (+UK) sample only (right panel) and could not be detected in vivo before or after DDAVP administration (left panel). The amino-terminal native 140 kDa fragment is present in plasma before and after UK treatment and is slightly more prominent after DDAVP infusion. The arrow marks the interface between the stacking (sample) and running gels.

shown that the increased proportion of fragments in IIA vWD was not a result of plasmin proteolysis.⁸ Rather, the fragments reacted with the same monoclonal antibodies that the 140 and 176 kDa fragments reacted with in normal plasma, thereby indicating that the IIA fragments resulted from a degradative process analogous to that operative in normal individuals. Similarly, the post-DDAVP increase in the 176 kDa fragment reported here was not the result of plasmin cleavage, even though plasminogen activator is released by DDAVP. Thus, the enzyme or enzymes responsible for the increased cleavage vWF in normal individuals, or in IIA vWD, is uncertain at present.

The infusion of DDAVP in normal individuals was followed by the appearance of multimers that were larger than those seen in the resting state and that disappeared over time (Fig 1). Using higher-resolution gels we observed that after DDAVP infusion the structure of each multimer changed; it showed an increase in the satellite bands (Fig 2). This increase in satellite bands is reminiscent of that seen in type IIA vWD,^{1,6} suggesting that in both situations they are the result of increased proteolysis.

After DDAVP administration, increased proportions of von Willebrand fragments circulate, but the mechanism by which this occurs is uncertain at present. DDAVP causes the release of larger, presumably more hemostatically effective, multimers from storage sites and also increases the overall concentration of vWF in plasma. It is possible that these larger multimers are more susceptible to normal degradative processes and thus are rapidly fragmented. Alternatively, DDAVP may release one or more enzymes or enzyme activators and in this manner accelerate the loss of large multimers. In either case, identifying the enzyme or enzymes responsible should allow the development of strategies for making DDAVP more effective, particularly in IIA vWD where the vWF appears to be more susceptible to cleavage.^{2,5}

Regulation of Thrombopoiesis: Effects of the Degree of Thrombocytopenia on Megakaryocyte Ploidy and Platelet Volume

By Laurence Corash, Huei Yin Chen, Jack Levin, Georgiann Baker, Helen Lu, and Yuen Mok

We have established a murine model and techniques with which to serially study thrombopoiesis after induction of experimental immune thrombocytopenia of variable severity and duration. Bone marrow megakaryocyte ploidy distribution was determined by using unfractionated bone marrow, a polyclonal megakaryocyte-specific probe, and two-color, fluorescence-activated flow cytometry. With these techniques, the modal megakaryocyte ploidy class in normal murine bone marrow was 16N. Serial studies of bone marrow megakaryocyte ploidy after the induction of acute, severe thrombocytopenia (platelet count, $<0.05 \times 10^6/\mu\text{L}$) demonstrated no detectable change in the ploidy distribution at 12, 24, and 36 hours after the onset of thrombocytopenia. At 48 hours, the modal ploidy class shifted from 16N to 32N, and the 64N class increased significantly ($P < .001$). The ploidy distribution returned to normal 120 hours after the onset of thrombocytopenia. A lesser degree of thrombocytopenia (platelet count reduction to 0.100 to $0.200 \times 10^6/\mu\text{L}$) delayed the modal ploidy class shift from 16N to 32N until 72 hours after the onset of thrombocytopenia. Chronic, severe thrombocytopenia

(platelet count, $<0.05 \times 10^6/\mu\text{L}$ for seven days) resulted in a modal ploidy class shift from 16N to 32N during the thrombocytopenic phase and an enhanced increase in the 64N megakaryocyte class during the recovery phase. Mean platelet volume (MPV) was simultaneously measured on isolated total platelet populations after induction of thrombocytopenia. MPV was significantly increased ($P < .001$) as early as eight hours after the onset of acute, severe thrombocytopenia, 40 hours before a shift in the ploidy distribution. Mild thrombocytopenia (platelet count reduction to $0.400 \times 10^6/\mu\text{L}$) was not associated with a ploidy shift but did result in a significantly increased MPV ($P < .001$). These studies demonstrate that the temporal relationship and magnitude of the effects of thrombocytopenia upon megakaryocyte ploidy distribution are dependent upon the degree and the duration of the thrombocytopenic stimulus and that the effects of experimental thrombocytopenia on platelet volume and megakaryocyte ploidy are dissociated.

© 1987 by Grune & Stratton, Inc.

THE MECHANISMS that regulate thrombopoiesis remain incompletely understood. Previous studies suggest that experimental, acute thrombocytopenia results in alterations of platelet volume,^{1,2} megakaryocyte cytoplasmic volume,³⁻⁷ stages of megakaryocyte maturation,^{1,3,4} megakaryocyte ploidy distribution,^{1,4,6,8,9} and megakaryocyte colony-forming cells (Meg-CFC).¹⁰⁻³¹ While these studies indicate that thrombopoiesis is responsive to fluctuations in the circulating platelet mass, considerable controversy persists concerning many aspects of thrombopoiesis, including the normal megakaryocyte ploidy distribution,^{9,14,15} the determinants of platelet volume,^{16,17} and the response of Meg-CFC to thrombocytopenia.^{18,19} A majority of studies of thrombopoietic regulation^{1,3,4,6,7,9} have primarily focused on the effects of severe thrombocytopenia and, with two exceptions,^{3,20} have not examined the effects of lesser degrees of thrombopoietic perturbation. Furthermore, relatively few studies have extensively characterized the temporal sequence and duration of the response of megakaryocytes or their precursors to acute or chronic perturbation of the circulating platelet mass.^{1,3,6,10,12,13} In addition, only one study has simultaneously examined the changes in megakaryocytes and circulating platelets in a serial fashion throughout the entire period of altered thrombopoiesis.¹

Previous efforts have been hampered by the lack of a suitable experimental model and techniques with which to measure the effects of perturbed thrombopoiesis on all three cellular compartments of thrombopoiesis: circulating platelets, recognizable megakaryocytes, and morphologically unrecognizable precursor cells. Advances in platelet isolation,²¹ analysis of megakaryocyte DNA content,⁹ and cultures that support the growth of megakaryocyte colonies from colony-forming cells²² now make more feasible a unified approach to the study of thrombopoiesis.

We have established a murine model and techniques to

extend the study of the regulation of thrombopoiesis. Previous reports by one of us have described the extended effects of acute and chronic, severe thrombocytopenia on Meg-CFC.^{10,11} The present report describes our use of a murine model to serially examine the effects of immune mediated thrombocytopenia of variable severity and duration on the ploidy distribution of bone marrow megakaryocytes and on the mean platelet volume (MPV) of circulating platelets.

MATERIALS AND METHODS

General techniques. C57/BL mice, with intact spleens, were used for all studies. Thrombocytopenia was induced by the intraperitoneal injection of guinea pig antimouse platelet serum (GP-PAS) that had been adsorbed against erythrocytes and leukocytes as previously described.¹⁰ Variable levels of thrombocytopenia were produced by adjusting the administered dose of GP-PAS; the level of thrombocytopenia was defined by the platelet count 12 or 24 hours

after administration of GP-PAS. Due to interindividual variation in response to GP-PAS, cohorts of animals with a uniform degree of thrombocytopenia were produced by the following procedure. A large group of animals were injected with a dose of GP-PAS calculated to produce the desired level of thrombocytopenia based upon prior experience. At 12 or 24 hours after antiserum injection, platelet counts were performed on blood samples obtained from the retroorbital venous plexus, and collected into EDTA- and heparin-coated capillary tubes (Drummond Scientific Co, Broomall, PA). Platelet counts were performed by using a described technique²³ with an electronic particle counter (Coulter Electronics, Hialeah, FL). The animals were grouped for further studies according to their platelet levels.

Collection of bone marrow cells. At designated time points, mice were sacrificed by cervical dislocation, and the bone marrow was flushed from the femurs and humeri with a small volume of CATCH medium¹⁴ supplemented with sodium citrate (0.38%), prostaglandin E₁ (PGE₁) (1.0 µg/mL), horse serum (5%), and DNAase (30.0 Kunitz U/mL) into a larger volume of the same supplemented medium. Bone marrow was harvested and pooled from two animals for each flow cytometric analysis. A total nucleated cell count was determined by counting the diluted cell suspension with a Coulter S Plus IV particle counter (Coulter). After counting, the cells were divided into two aliquots containing 2 to 4 × 10⁷ cells each in 2 to 5 mL of supplemented CATCH medium. The cells were centrifuged at either 70 or 350 g for five minutes at 23°C, the supernatant fraction was aspirated, and the cells were resuspended in 100 µL of supplemented CATCH medium.

Identification of megakaryocytes and measurement of megakaryocyte DNA. Cells were defined as megakaryocytes and electronically selected from the total nucleated bone marrow cell population by a modification of the two-color fluorescence-activated flow cytometry technique originally described by Jackson and coworkers.⁹ Megakaryocytes were identified by labeling with a cell class-specific probe directed against multiple surface constituents. The probe used in these experiments consisted of a high-titer, polyclonal rabbit antimouse platelet serum (R-PAS) that had been adsorbed against mouse erythrocytes and leukocytes.

The potency and specificity of this reagent was evaluated by the following methods. First, the antiserum was assayed in a fluorescence-activated flow assay to determine the potency of binding to isolated mouse platelets and to establish the maximum dilution sufficient to produce adequate platelet labeling. This assay technique is based on our described method for the measurement of platelet-associated immunoglobulin.²⁴ Serial dilutions of the R-PAS were incubated with 5 × 10⁶ mouse platelets, and the binding of antibody was detected by using a second-step reagent consisting of biotin-conjugated goat antirabbit immunoglobulin Fab 2' fragment (GAR-Fab 2') (Dako Laboratories, Santa Barbara, CA) directed against all major heavy chain classes. The fluorescence detection system consisted of avidin-conjugated fluorescein. Labeled cells were analyzed in a Becton Dickinson Research Analyzer (Becton Dickinson, Mountain View, CA) as described.²⁴

The specificity of the R-PAS reagent was evaluated by an immunoblot assay with solubilized murine platelet proteins as the target antigens by utilizing our recently described method for human platelets.²⁵ The cell class specificity of the R-PAS reagent for murine megakaryocytes was also evaluated by examining the binding of R-PAS to murine bone marrow cells by light microscopy with immunocytochemical techniques.²⁶ Using these assay systems, we determined that a 1:4,000 dilution of the R-PAS in phosphate-buffered saline (pH 7.4) produced maximal platelet surface labeling. The immunoblot analyses demonstrated that the R-PAS reagent was active against multiple murine platelet proteins ranging from less than 45 kilodaltons (kd) to more than 300 kd, the resolving limits of

the gel system. The most intense labeling occurred against the region of the gel that contained the platelet glycoprotein IIb/IIIa complex. Microscopy with immunoperoxidase-labeled reagents demonstrated no reactivity of the R-PAS against nonmegakaryocytic bone marrow cells, whereas megakaryocytes of all three maturational stages³ were labeled by the polyclonal R-PAS.²⁶

Based upon the preceding observations, the following conditions were used for labeling of megakaryocytes in the two-color fluorescence DNA assay. An aliquot containing 2 to 4 × 10⁷ washed bone marrow cells was incubated in 900 µL of a 1:4,000 dilution of R-PAS for 60 minutes at 4°C. An identical aliquot of bone marrow cells was incubated with a 1:4,000 dilution of nonimmune, normal rabbit serum (NRS) to serve as a negatively stained control sample. From this point, the NRS control and the R-PAS-labeled aliquots were treated similarly. The cells, which had been incubated with either R-PAS or NRS, were washed three times with cold CATCH medium supplemented with 0.38% citrate and PGE₁ (1.0 µg/mL) (CATCH-PGE-citrate), suspended in 100 µL of CATCH-PGE-citrate medium, and then labeled with 200 µL of a 1:20 dilution of biotin-conjugated GAR-Fab 2' for 60 minutes at 4°C. Subsequently, the cell aliquots were washed three times with cold CATCH-PGE-citrate medium, resuspended in 100 µL of CATCH-PGE-citrate medium, and incubated for 30 minutes at 4°C with 400 µL of a 1:20 dilution of avidin-fluorescein isothiocyanate (FITC; 250 µg/mL, Becton Dickinson). After fluorescein labeling, the cells were washed three times with cold CATCH-PGE-citrate medium and resuspended in 0.67 mL of hypotonic citrate-saline buffer (100 mOsm/L) containing 1% bovine serum albumin (BSA) and propidium iodide (50 µg/mL). The 100-mOsm/L hypotonic solution permitted adequate penetration of the cells by propidium iodide for DNA staining with preservation of megakaryocyte cellular morphology. Cellular morphology was evaluated by microscopic examination of cytocentrifuge preparations of samples of the bone marrow cell suspensions stained with modified Romanowsky stain.²⁷ The cells were maintained in the hypotonic propidium iodide solution at 4°C for two hours to permit DNA staining by propidium iodide, treated with freshly prepared RNase (50 µg/mL) for 30 minutes at 23°C, and filtered through nylon mesh (75-µm pore diameter) immediately prior to fluorescence-activated cell analysis. Cell recovery after propidium iodide staining was determined for a number of bone marrow samples (N = 6) by performing a second total nucleated cell count. Total nucleated cell recovery averaged 56.7% ± 6.3% (SD).

The fluorescein and propidium iodide channels of the flow cytometer (Becton Dickinson FACS Research Analyzer) were aligned by using 5.76-µm beads. Fluorescence activation was produced with the 488-nm line of a high-pressure Hg light source. The analyzer was equipped with a 75-µm orifice, and the following photomultiplier (PMT) conditions were used: fluorescein channel PMT = 250 V, log scale; propidium iodide channel PMT = 250 V, log scale. The data were accumulated in a single-parameter mode and stored on a hard disk for subsequent analysis. Bone marrow cells were analyzed at a flow rate of 200 to 400 cells per second without sample agitation.

Electronic selection of megakaryocytes from the unfractionated bone marrow cell population requires the positioning of an electronic fluorescein gate, or "green gate," to discriminate the megakaryocyte subpopulation from the total bone marrow cell population. This selected subpopulation was then analyzed for DNA content by propidium iodide staining in the second analyzer channel. Instead of setting the fluorescein gate at the point where 99% of the signals from cells labeled with NRS were excluded as in the method of Jackson et al.,⁹ we analyzed the total cell population after labeling with both the NRS and R-PAS reagents and then selected a point that was beyond the 99% exclusion level and at the nadir of the fluorescence distribution between the unlabeled and labeled cell populations (Fig 1A). This alternative green gate, subsequently

Fig 1. (A) The fluorescence distribution of unfractionated bone marrow cells is shown after labeling with the megakaryocyte-specific antisera (R-PAS) or NRS. Note that the initial portions of these two distributions overlap. The abscissa indicates fluorescence intensity (FL 1-logarithmic scale), and the ordinate indicates the cell number (f) at full scale. The leftmost vertical marker (99%) indicates the 99% electronic exclusion gate that selects the 1% brightest cells, whereas the marker to the right (+) indicates the nadir between the unlabeled population (to the left) and the labeled population (to the right) of bone marrow cells. The latter marker is referred to as the positive green gate marker. The small fraction of cells to the right of the positive green gate marker was designated as the megakaryocyte population and was subjected to DNA analysis as shown in B. (B) The distribution of the DNA content is shown for the selected cell population, which has been electronically isolated in A on the basis of surface fluorescence. The abscissa indicates fluorescence intensity (FL 2-logarithmic scale) and the ordinate is cell number (f) at full scale. The peaks are as follows from left to right: 2N, 4N, 8N, 16N, 32N, and 64N. One thousand selected cells were analyzed to obtain the megakaryocyte ploidy distribution.

termed the "positive green gate," is a more conservative gating point than the 99% exclusion point and produced DNA distributions with discrete separations of the different megakaryocyte ploidy classes (Fig 1B).

The analyzer threshold was adjusted by using the propidium iodide channel to exclude subcellular debris and to include all cells with a DNA content of 2N or greater. The megakaryocyte DNA content was measured in all cells with fluorescence greater than the positive green gate marker and with a DNA content of 2N or greater. For determination of the megakaryocyte DNA distribution, each sample was analyzed for a time period sufficient to accumulate between 3,000 and 4,000 megakaryocytes, as defined by cell surface labeling. The major fluorescent peak for DNA of the nonmegakaryocyte cells was determined in each analysis and was used as the 2N standard to set windows of equal width for the 2N to 128N ploidy classes.

To evaluate the possibility that intraperitoneal administration of GP-PAS could result in direct *in vivo* binding of antibody to megakaryocytes as well as to platelets, we determined whether our assay system for the detection of megakaryocytes using biotin-conjugated GAR-Fab 2' could also detect GP-PAS bound to mouse platelet or megakaryocyte surface proteins. When mouse platelets were incubated with a 1:4,000 dilution of GP-PAS instead of R-PAS, we observed labeling with the biotin-conjugated GAR-Fab 2' fragments that was equal to that observed with the R-PAS first-step reagent. This indicates that if significant direct *in vivo* labeling of mouse megakaryocytes occurred it could potentially be detected by the second-step reagent in the two-color assay system.

Measurement of MPV. Blood for the measurement of the MPV was obtained by puncture of the retroorbital venous plexus with EDTA- and heparin-coated capillary tubes. Seventy microliters of blood was drawn into each of two glass capillary tubes, and the blood was immediately added to 330 μ L of buffered anticoagulant solution containing the following final concentrations: sodium citrate, 13 mmol/L; EDTA, 1 mmol/L; PGE₁, 1 μ g/mL; and theophylline, 0.18

mg/mL. Platelet volume studies from severely thrombocytopenic animals required the collection of up to seven capillary tubes per animal. Under these conditions, three capillary tubes were added to each 330- μ L volume of buffered anticoagulant solution. Samples from two to five mice, either controls or treated animals, were pooled and layered over a discontinuous arabinogalactan gradient composed of 10% (wt/wt) and 20.5% (wt/wt) layers as previously described for rabbit platelets.²¹ The gradients were centrifuged at 20,000 g for ten minutes at 23°C to separate the platelets from the plasma proteins, erythrocytes, and granulocytes. Lymphocytes and monocytes exhibit a density distribution that overlaps that of platelets; since these leukocytes cosediment with platelets, they were electronically excluded from the platelet size distribution by setting an upper volume threshold.²¹ The MPV was measured with an electrical impedance cell analyzer (Particle Data, Inc, Chicago) equipped with a 48- μ m orifice tube, a logarithmic analyzer, and a PDP 11A computer. This instrument was calibrated with 2.02- μ m-diameter latex beads as previously described.²¹ The MPV was measured as the geometric mean of the platelet volume distribution curve and expressed in femtoliters. Contaminating erythrocytes were excluded by use of an electronic upper threshold, and a Gaussian curve-fitting program was utilized to complete the upper end of the platelet volume distribution curve.

Statistical analysis. The means and SD of the bone marrow megakaryocyte ploidy class distributions, platelet counts, and MPVs were computed by standard methods. Statistical comparisons of the MPV between the normal murine population and the experimental groups were performed with a standard *t* test.²⁸ Statistical comparisons of the megakaryocyte ploidy distributions between the normal population and the experimental groups were performed with the Mann-Whitney rank test.²⁹

RESULTS

Megakaryocyte DNA distribution in mice with normal platelet levels. The distribution of DNA content in murine bone marrow megakaryocytes was measured by using bone marrow harvested from normal animals. The positive green gate marker technique produced megakaryocyte DNA distributions with clear separations between the ploidy classes (Fig 1B). Under our operating conditions, the observed

Fig 2. The frequency distribution of megakaryocyte DNA content in the bone marrow of normal mice is shown. Ploidy classes from 2N to 256N are indicated on the abscissa. The relative mean frequency of each ploidy class ± 1 SD is indicated as a percentage of the total megakaryocyte population on the ordinate. The 16N cell class, the normal modal class, is identified by the solid black bar for reference. Twenty-five analyses were performed with the positive green gate technique; each consisted of the pooled bone marrow from two animals. The average number of megakaryocytes analyzed in each experiment to determine the ploidy distribution was $3,413 \pm 1,273$ (SD).

Fig 3. The frequency distribution of megakaryocyte DNA content after the induction of various degrees of acute thrombocytopenia is shown. Each sample consisted of the pooled bone marrow from two animals. The abscissa indicates the ploidy class from 2N to 64N, and the ordinate indicates the relative frequency (in percentage) of the various ploidy classes. The time after GP-PAS administration at which bone marrow samples were obtained is indicated in hours along the lower abscissa and is the same for each experimental series. The mean platelet count ($\times 10^6/\mu\text{L}$) of the animals studied at each time point is indicated above the individual histograms. The number of experiments performed at each time point is indicated in parentheses, except where only a single experiment was performed. Absence of a ploidy histogram indicates that a DNA study was not performed at that time point, but the mean platelet count is indicated. The mean platelet counts ($\times 10^6/\mu\text{L}$) 24 hours after GP-PAS administration were as follows: A, 0.031; B, 0.154; C, 0.244; D, 0.312. The normal modal ploidy class was 16N. In each histogram, the relative frequency of the 16N cell class is identified by the solid black bar.

modal megakaryocyte ploidy class was 16N (Fig 2). We calculated the fraction of cells in the bone marrow cell suspension that were immunologically identified as megakaryocytes. Under these conditions, this measurement provides an approximate estimate of megakaryocyte frequency in unfractionated bone marrow. The mean value for 25 experiments, each consisting of two animals, was $0.496\% \pm 0.35\%$ SD.

Effects of acute, severe thrombocytopenia on the distribution of megakaryocyte DNA and MPV. Acute, severe thrombocytopenia (platelet count reduction to $<0.05 \times 10^6/\mu\text{L}$, 5% of normal) 12 hours after PAS administration resulted in no detectable change in the distribution of megakaryocyte ploidy at 12, 24, or 36 hours after GP-PAS administration (Fig 3A). Although the frequency of the 32N class increased at 36 hours after GP-PAS administration, this difference was not statistically significant ($P = .07$). Forty-eight hours after administration of GP-PAS, a shift in the modal ploidy class from 16N to 32N was consistently observed (Fig 3A). The frequency of 64N cells also was significantly increased ($P < .001$) at 48 hours after induction of thrombocytopenia and remained increased until 96 hours. At 48 hours after GP-PAS administration, the platelet level ($0.125 \times 10^6/\mu\text{L}$) had begun to return toward normal (Fig 4). However, the shift in the modal ploidy class from 16N to 32N persisted until 84 hours after administration of GP-PAS. At 96 hours after administration of GP-PAS, the frequency of the 32N class was still increased ($P < .02$), but the 32N class was no longer the modal class. The megakaryocyte DNA distribution returned to normal 120 hours after PAS administration. Animals treated with

nonimmune guinea pig serum (NGPS) did not demonstrate any significant changes in megakaryocyte DNA distribution compared with untreated controls.

Bone marrow cells obtained from animals treated with GP-PAS and then exposed only to NRS *in vitro* did not show any evidence of *in vivo* megakaryocyte labeling, and labeling could only be demonstrated after *in vitro* exposure of the cells to R-PAS. This suggests that binding of intraperitoneally administered GP-PAS to native megakaryocytes was not present 24 hours after PAS administration, although it is possible that a small amount of binding could have occurred earlier or at a concentration that was below the detection threshold of the assay. Platelets isolated from animals 24 hours after GP-PAS administration also did not demonstrate guinea pig immunoglobulin on the surface by examination with immunoelectron microscopy.³⁰

MPV was measured from 8 to 96 hours after the induction of acute, severe thrombocytopenia (reduction of platelet count to less than $0.05 \times 10^6/\mu\text{L}$) (Table 1). MPV was significantly increased ($P < .001$) at eight hours after the administration of GP-PAS. The peak increment in MPV occurred at 24 hours, and MPV then slowly declined to the normal range at 96 hours. Importantly, MPV decreased continuously from the peak level, although it remained significantly elevated ($P < .001$) at each time point, as the platelet level increased dramatically during the 36- to 84-hour period after induction of acute thrombocytopenia (Table 1).

Effects of variable degrees of acute thrombocytopenia on megakaryocyte DNA distribution. The effect of the severity of thrombocytopenia on megakaryocyte DNA distri-

Fig 4. The time course for recovery of platelet levels after the induction of experimental thrombocytopenia is shown. The platelet count ($\times 10^6/\mu\text{L}$) is indicated on the ordinate and time (h) is indicated on the abscissa. Platelet counts during recovery from various degrees of thrombocytopenia were obtained from variable numbers of mice in each experimental group: 12 hours, 12; 24 hours, 6 to 24; 36 hours, 2; 48 hours, 2 to 8; 60 hours, 2; 72 hours, 2 to 11; 84 hours, 2; 96 hours, 2 to 8; 120 hours, 2 to 3. For the group with chronic thrombocytopenia the following numbers of animals were used at the respective time points during the initial treatment period: 24 hours, 30; 48 hours, 2; 72 hours, 8; 120 hours, 5. During the recovery phase from chronic thrombocytopenia the following numbers of animals were used to determine the platelet counts at the respective time points: 24 hours, 20; 48 hours, 6; 72 hours, 5; 96 hours, 5; 120 hours, 4. The following symbols denote the level of thrombocytopenia 24 hours after administration of GP-PAS: solid circle, $<0.05 \times 10^6/\mu\text{L}$; open circle, 0.100 to $0.200 \times 10^6/\mu\text{L}$; solid triangle, 0.200 to $0.300 \times 10^6/\mu\text{L}$; open triangle, 0.300 to $0.400 \times 10^6/\mu\text{L}$, and solid square, chronic thrombocytopenia of $<0.05 \times 10^6/\mu\text{L}$. The arrows below the abscissa indicate the times of GP-PAS administration during the chronic thrombocytopenia experiment. The large arrow indicates the initial GP-PAS injection in all experiments. The time points with the suffix R indicate the recovery phase of the chronic thrombocytopenia experiment.

bution was evaluated by adjusting the dose of GP-PAS to produce lesser degrees of thrombocytopenia. Animals were treated with various single doses of GP-PAS and placed according to the platelet count 24 hours after GP-PAS administration into one of three groups: 0.100 to 0.200×10^6 platelets/ μL , 0.200 to 0.300×10^6 platelets/ μL , and 0.300 to

Table 1. The Effect of Acute Severe Thrombocytopenia on MPV

PC	1.62	.02	.03	.02	.10	.16	.58	1.42	2.00
SD	0.40	0.01	0.02	0.03	0.03	0.06	0.19	0.70	1.26

NOTE. C indicates a normal control population. The MPV of the normal population, $4.6 \text{ fL} \pm 0.5 \text{ SD}$, was used for statistical comparisons with the treated population. The time after GP-PAS administration is indicated in hours, MPV is expressed in femtoliters, and the platelet count (PC) $\times 10^6/\mu\text{L}$ with the SD of the mean is shown. N represents the number of individual animals utilized at each time point to determine the platelet count. Blood from these animals was pooled to measure MPV at each time point in two separate experiments. MPV of control animals was obtained from individual animals. A separate group of animals was used for the ploidy analyses.

* $P < .001$.

† $P < .01$.

0.400×10^6 platelets/ μL . The megakaryocyte DNA distribution (Figure 3B to D) and the time course of recovery of the platelet level (Fig 4) were serially measured. Reduction of the platelet level to 0.100 to 0.200×10^6 platelets/ μL (mean, $0.154 \pm 0.037 \text{ [SD]} \times 10^6$ platelets/ μL ; range, 0.098 to 0.232×10^6 platelets/ μL) did not produce a shift in the modal ploidy class at 48 hours after GP-PAS administration (Fig 3B), the time point at which a ploidy shift was consistently observed after severe, acute thrombocytopenia (Fig 3A). However, at 48 hours after administration of GP-PAS, the relative frequency of 32N megakaryocytes increased to 28%, the upper limit of the normal range for the 32N class ($P < .05$). More importantly, at 72 hours after GP-PAS administration, there was a shift in the modal megakaryocyte ploidy class from 16N to 32N (Fig 3B). Therefore, the shift in ploidy class in response to acute thrombocytopenia, which was always observed at 48 hours after severe thrombocytopenia (platelet level, $<0.05 \times 10^6$ platelets/ μL), was delayed for an additional 24 hours when the stimulus of thrombocytopenia was less severe. At 96 hours after the induction of moderate thrombocytopenia (0.100 to 0.200×10^6 platelets/ μL), the modal ploidy class reverted to 16N, and a complete return to the baseline DNA distribution was observed 120 hours after GP-PAS injection. No significant increment in the 64N megakaryocyte class was observed at any time.

Reduction of the platelet level to 0.200 to 0.300×10^6 platelets/ μL (mean, $0.244 \pm 0.026 \text{ [SD]} \times 10^6$ platelets/ μL ; range, 0.227 to 0.296×10^6 platelets/ μL) also resulted in a delayed shift of the megakaryocyte DNA distribution similar to that observed with the preceding experimental group (Fig 3C). The 32N megakaryocyte class was not significantly increased at 48 hours after administration of GP-PAS ($P > .05$), and a shift in the modal ploidy class from 16N to 32N occurred at 72 hours. Additional experiments (Fig 3D) in which the platelet level was reduced to 0.300 to 0.400×10^6 platelets/ μL (mean, $0.354 \pm 0.059 \text{ [SD]} \times 10^6$ platelets/ μL ; range, 0.227 to 0.441×10^6 platelets/ μL) demonstrated no significant change in frequency of the 32N class at any time.

When very moderate thrombocytopenia (platelet count nadir of 0.400×10^6 platelets/ μL at 16 hours after GP-PAS injection) was produced, a highly significant change in MPV occurred as early as 12 hours after administration of GP-PAS (Table 2, group B) and persisted until 144 hours after GP-PAS administration. It should be noted that the platelet count nadir was probably missed for animal group A (Table 2) due to the long sampling interval from four to 24 hours after GP-PAS injection. The increase in platelet volume during this experiment reached a peak 24 hours after administration of GP-PAS, at which time the megakaryocyte ploidy distribution was entirely within the normal range in response to slightly greater thrombocytopenia (Fig 3D). Thus, an effect on platelet volume was produced by a level of thrombocytopenia that did not alter megakaryocyte DNA distribution during the 96-hour period after moderate thrombocytopenia (Fig 3D).

Effects of chronic, severe thrombocytopenia on megakaryocyte DNA distribution. Chronic, severe thrombocytopenia was induced by a reduction of the platelet level to less

Table 2. The Effect of Acute Moderate Thrombocytopenia on MPV

Group A						
Time	C	4	24	48	72	144
MPV	4.1	5.3*	6.3†	6.3†	5.7†	5.6†
PC	1.24	1.1	0.95	0.85	1.65	2.50
SD	0.11	0.56	0.28	0.17	0.68	1.13
Group B

MPV	4.1	5.7†	5.6†	5.6†	6.3†	5.6†
PC	1.24	0.65	0.40	0.75	1.2	2.2
SD	0.11	0.17	0.14	0.19	0.59	1.16

NOTE. Two animal groups (A and B) were used to obtain serial measurements of MPV after the induction of thrombocytopenia. A separate group of animals was used for the ploidy analyses. Group A was studied at 4, 24, 48, 72, and 144 hours, and group B was studied at 12, 16, 36, 64, and 108 hours after GP-PAS administration. MPV is expressed in femtoliters, and the platelet count $\times 10^6/\mu\text{L}$ (PC) is indicated with the SD of the mean. MPV and platelet count data at each time point represent mean values from eight individual animals. The MPV of 22 normal control animals (C) was $4.1 \text{ fL} \pm 0.5 \text{ SD}$. Statistical comparisons were made with this control population.

* $P < .005$.

† $P < .001$.

than 0.05×10^6 platelets/ μL and was then maintained at approximately that level by repeated administration of GP-PAS every other day for a seven-day period (Fig 4). After 120 hours of sustained, marked reduction in platelet levels (Fig 4), the bone marrow megakaryocyte DNA distribution was determined (Fig 5). The modal ploidy class was 32N, and the frequency of the 64N class was significantly increased ($P < .05$). Twenty-four hours after discontinuation of chronic GP-PAS administration, the mean platelet level ($\times 10^6/\mu\text{L}$) of the entire group of mice ($n = 21$) was 0.033 ± 0.016 (SD) with a range from 0.019 to 0.064. At this time, eight days after initiation of thrombocytopenia, the frequency of 16N and 32N cells was approximately equal, and the frequency of the 32N cells remained significantly increased compared with normal ($P < .05$) (Fig 5). Forty-eight hours after the last GP-PAS dose, 32N cells again constituted the modal class, and the 64N cells constituted 24.9% of the megakaryocyte population. This latter change was the largest increment in 64N cells observed in response to thrombocytopenia and was significant compared with the normal DNA distribution ($P < .05$). As platelet recovery occurred (Fig 4), the frequency of both 32N and 64N cell classes declined (Fig 5), although both remained significantly elevated until 120 hours after the last GP-PAS dose, at which time the distribution returned to normal.

DISCUSSION

Previous studies have provided limited and conflicting information concerning the regulation of thrombopoiesis after experimental thrombocytopenia. Ebbe et al³ demonstrated an increase in rat megakaryocyte volume that reached a maximum 48 hours after a 92% reduction of the platelet level by exchange transfusion. Extreme thrombocytopenia (99.9% reduction of the platelet level induced by platelet antiserum) produced a larger increase in mega-

Fig 5. The frequency distribution of megakaryocyte DNA content after the induction of chronic, severe thrombocytopenia (platelet count $< 0.05 \times 10^6/\mu\text{L}$) is shown. Studies were performed after 120 hours of chronic thrombocytopenia (120 CT time point) and at 24, 48, 72, 96, and 120 hours of the recovery phase after cessation of administration of GP-PAS. The recovery time points are denoted by the suffix R. The ploidy classes from 2N to 64N are indicated along the abscissa, and the relative frequency of each class is indicated as a percentage of the total megakaryocyte population on the ordinate. The 16N cell class is identified by the solid black bar for reference. The mean platelet count ($\times 10^6/\mu\text{L}$) for the animals used for the ploidy distribution analyses at each time point is indicated above the individual histograms, and the number of experiments performed at each time point is indicated in the parentheses.

karyocyte cell volume than observed after a 92% reduction in the platelet level. Other studies by Harker,⁴ also using rats, extended these observations to demonstrate a parallel shift in megakaryocyte "nuclear number" as well as volume after four days and ten days of an 80% reduction in the platelet level. However, Harker did not directly determine the megakaryocyte DNA content. Studies by Penington and Olsen⁶ and Odell and coworkers¹ using direct measurement of megakaryocyte DNA found the normal rat megakaryocyte modal ploidy class to be 16N and observed that induction of acute, severe thrombocytopenia resulted in a shift of the modal class from 16N to 32N 48 hours after reduction in the platelet level. Odell et al¹ described an early increase in platelet size 18 hours after induction of thrombocytopenia and noted that the maximum increase in platelet size preceded the peak increase in both megakaryocyte volume and ploidy distribution by 30 hours.

After six days of variable, chronic thrombocytopenia, Martin et al⁷ observed a marked increase in total megakaryocyte cell volume, cytoplasmic volume, and nuclear volume. MPV increased by approximately 10% compared with the control during the first four days and then rapidly increased by an additional 30% at the sixth day. In a second paper,⁸ these workers reported a shift from the normal modal megakaryocyte ploidy class of 16N to 32N after 24 hours of thrombocytopenia (90% reduction in platelet level); a similar shift also was observed after six days of chronic thrombocytopenia. In a third study, Trowbridge and Martin² produced an 86% reduction in the platelet level of rabbits and observed a 27% increase in MPV six hours after the induction of thrombocytopenia. However, they observed no change in the modal megakaryocyte ploidy class from their normal control value of 32N either two hours or 24 hours after the onset of thrombocytopenia, although there was an increase in the relative frequency of the 32N class. Martin et al concluded that thrombocytopenia results in an increase in megakaryo-

cyte ploidy and cytoplasmic volume with subsequent production of larger platelets.⁸

Using a modified two-color technique based on the method of Jackson et al,⁹ we have observed that the modal megakaryocyte ploidy class in mice with normal platelet levels is 16N. Our megakaryocyte ploidy distributions are similar to those of Jackson et al although the use of the more conservative megakaryocyte selection gate reduced the observed frequency of 2N and 4N megakaryocytes. These differences may be partially due to species variation as well. Our determinations of the normal murine megakaryocyte ploidy distribution are in general agreement with the earlier observations of Odell et al and Penington and Olsen using the Feulgen microdensitometric technique with rat bone marrow smears,^{6,31} those of Worthington et al³² with a single-color flow cytometric technique, and those of Mayer et al³³ using immunofluorescent identification of megakaryocytes followed by Feulgen staining to measure the DNA content. In each of these studies^{6,9,31-33} the 2N and 4N classes were infrequent, 16N was the modal class, and 8N cells ranged in frequency from 8.1% to 23.0%. The results from these investigations and those of the present study do not agree with the observations of other workers who have used single-color fluorescence-activated flow cytometry and found that 8N is the most common ploidy class.^{14,15} Jackson et al suggest that this discrepancy may be due in part to failure of the single-color flow technique to exclude cell aggregates,⁹ a problem that is minimized by the two-color technique.

The two-color technique not only clearly resolves the individual ploidy classes but also is advantageous because of the large numbers of cells analyzed and the use of a megakaryocyte selection technique that is independent of morphology. Immunologic identification of megakaryocytes could potentially underestimate the number of megakaryocytes if the megakaryocyte-specific probe failed to detect a portion of the megakaryocyte population. However, the probe used in the present studies was found to be sensitive to a broad spectrum of murine platelet proteins, which indicates that there should be broad sensitivity for megakaryocyte proteins as well. The studies of Rabellino et al³⁴ demonstrate that the small, immature human megakaryocytes express the major platelet glycoproteins Ib, IIb, and IIIa. Jackson has demonstrated good correlation between the identification of rat megakaryocytes with PAS and detection of acetylcholinesterase.³⁵ The recent report by Ishibashi et al³⁶ also provides evidence that immature, morphologically unrecognizable megakaryocytes are identified by a monoclonal antibody directed against the glycoprotein IIb/IIIa complex. Since it is possible that the electronic gating technique could exclude low-ploidy megakaryocytes that contain low levels of surface fluorescence, we performed additional experiments using dual-parameter analysis in which the gate was further reduced below the standard positive green gate. This less-restrictive gating technique did not significantly increase the frequency of 2N, 4N, or 8N class megakaryocytes (data not shown). Our estimate of the frequency of megakaryocytes in normal murine bone marrow (0.496%) is in approximate agreement with earlier immunofluorescent microscopic determinations using murine marrow³³ and is in the range of

estimates obtained by a number of workers using rodents and a variety of techniques.³⁷⁻³⁹

We have demonstrated that the modal ploidy class shifts from 16N to 32N 48 hours after the induction of acute, severe thrombocytopenia. The shift is consistently initially observed 48 hours after administration of antiserum, persists until 84 hours after GP-PAS administration, and then reverts to normal 120 hours after the onset of thrombocytopenia. Jackson et al⁹ also observed a shift in the megakaryocyte ploidy distribution of rats 48 hours after the onset of thrombocytopenia, but the more frequent sampling in the present study clearly documented that no shift in the modal ploidy class was observed until the 48-hour time point.

The degree of thrombocytopenia in the study of Ebbe et al³ at which a significant increase in megakaryocyte cytoplasmic volume was observed is similar to that in our study of moderate thrombocytopenia (0.300 to 0.400×10^6 platelets/ μL 24 hours after GP-PAS administration). Under these conditions, we observed no significant change in the megakaryocyte ploidy distribution during the entire five-day period of observation (Fig 3D). Furthermore, MPV increased significantly 12 hours after GP-PAS administration in mice, with even a lesser reduction of platelet levels (Table 2). After acute severe thrombocytopenia (platelet count reduction to less than 0.05×10^6 platelets/ μL after administration of GP-PAS), we observed an increase in MPV 40 hours prior to a significant effect on the megakaryocyte ploidy distribution and 28 hours before the initial increase in the proportion of 32N megakaryocytes. Our observations indicate that the increases in platelet volume after acute thrombocytopenia clearly precede and therefore are dissociated from major changes in the megakaryocyte ploidy distribution; these increases constitute the initial response to reduced levels of circulating platelets, even when the degree of diminution of the circulating platelet mass is insufficient to produce a detectable alteration in megakaryocyte DNA content.

Moderate degrees of thrombocytopenia (reduction in platelet levels to approximately 10% to 20% of the normal level) resulted in a more delayed shift of the ploidy distribution. Very moderate thrombocytopenia (reduction in platelet level to 40% of normal) did not produce a shift in the modal ploidy class even as late as 96 hours after GP-PAS administration, although platelet volume was increased. These results suggest that the effect of thrombocytopenia on nuclear endoreduplication is modulated by the magnitude of the stimulus. Pertinently, Odell and Shelton⁴⁰ reported that endomitosis was not significantly increased in megakaryocytes unless platelet levels were reduced to less than 50% of normal.

The present studies of chronic, severe thrombocytopenia indicated that the megakaryocyte ploidy distribution remained significantly shifted during persistent thrombocytopenia and that the recovery phase was associated with a more marked increase in the 64N cell class than was observed during recovery from acute thrombocytopenia (Fig 5). This increased proportion of 64N class megakaryocytes may also explain the more rapid rate of platelet recovery observed in response to chronic thrombocytopenia as com-

pared with that after acute, severe thrombocytopenia (Fig 4). It is of interest that the megakaryocyte DNA distribution returned to normal 120 hours after discontinuation of platelet antiserum regardless of the magnitude or duration of the shift in the megakaryocyte DNA distribution. The present studies are consistent with the earlier results of Penington and Olsen.⁶ The lesser increase in the proportion of 32N megakaryocytes observed by Penington and Olsen⁶ is likely

due to their less frequent schedule of platelet antiserum administration, which probably did not produce as severe and consistent a period of prolonged thrombocytopenia as did our administration of antiserum at 48-hour intervals (Fig 4). Overall, our data demonstrate that the magnitude and temporal sequence of alterations that follow the induction of thrombocytopenia depend upon the magnitude and duration of the thrombocytopenic stimulus.

Clonal Immunoglobulin Gene Rearrangements in Tissues Involved by Hodgkin's Disease

By Marja G.L. Brinker, Sibrand Poppema, Charles H.C.M. Buys, Wim Timens, Jan Osinga, and Lydia Visser

The nature of Reed-Sternberg cells, the abnormal cells of Hodgkin's disease, is controversial. Morphological and immunologic marker studies suggested different cells of origin. To investigate a possible B or T cell origin, immunoglobulin and T cell receptor gene analyses were performed on tissues from 11 patients in early and late stages of Hodgkin's disease. In addition, the immunologic marker patterns of the Reed-Sternberg cells were determined.

Rearrangements of immunoglobulin heavy- and light-chain genes were detected in tissues from five patients, particularly in late stages of the disease when lymphocyte depletion had occurred. No rearrangements of T cell receptor genes were found. The results indicate that clonal immunoglobulin gene rearrangements can be detected in tissues involved by Hodgkin's disease.

THE NATURE OF REED-STERNBERG cells, the abnormal cells of Hodgkin's disease, is controversial. There is no formal proof that Reed-Sternberg cells in Hodgkin's disease constitute a monoclonal population. T cells, B cells, and macrophages have been implicated as the cells of origin of Reed-Sternberg cells.¹⁻³ Cell lines derived from tissue or pleural fluid involved by Hodgkin's disease may contribute to the solution of this problem; however, it is usually not possible to obtain absolute proof for the Reed-Sternberg cell origin of such cell lines.⁴⁻⁶ Because Reed-Sternberg cells do not produce detectable amounts of immunoglobulins, no firm evidence for a B cell origin is available. On the other hand, no reactivity with specific anti-T cell or antimacrophage antibodies could be demonstrated.⁷ Recently, some monoclonal antibodies prepared against a true histiocytic cell line were reported to be reactive with Reed-Sternberg cells.⁸ Reactivity with antibodies like Ki-1⁹ and Leu M1¹⁰ does not indicate a particular cell of origin of Reed-Sternberg cells. In some cases Reed-Sternberg cells are reactive with monoclonal anti-B cell reagents,¹¹⁻¹³ and in lymphocyte-predominant Hodgkin's disease the presence of J chains has been demonstrated in lymphocytic and histiocytic (L&H)-type Reed-Sternberg cells, thereby indicating the B cell origin of this type of Reed-Sternberg cell.^{14,15}

During the past few years, it has been shown that rearrangements of immunoglobulin genes can be demonstrated in clonal populations of B cells not or not yet producing immunoglobulin¹⁶ and, similarly, that rearrangements of T cell receptor genes can be demonstrated in clonal T cell populations.¹⁷ Here we describe the results of immunoglobulin and T cell receptor gene analysis in tissue samples of 11 patients with Hodgkin's disease.

MATERIALS AND METHODS

Tissue selection. Tissue specimens of 11 patients with Hodgkin's disease were studied. In all cases the original diagnosis was made on hematoxylin and eosin (H&E)-stained paraffin or glycol-methacrylate-embedded lymph node tissue sections. The cases were selected for the presence of relatively high numbers of Reed-Sternberg cells. In all cases the slides were reviewed by three expert lymphoma pathologists. Histological subtyping was performed according to the Rye classification.¹⁸ Autopsy tissue was available in patients 3, 4, and 5, who had clinical stage IV nodular sclerosis or the mixed-cellularity type of Hodgkin's disease with poor responses to chemotherapy. At autopsy in 1977, 1978, and 1984, respectively, we obtained at least 20 frozen tissue blocks of macroscopically vital tumor tissue in lung and liver, and these blocks were kept at -80°C. Frozen tissue blocks for the present study were selected on the basis of H&E-stained frozen tissue sections to ensure a high concentration of Reed-Sternberg cells and mononuclear variants and minimal necrosis or fibrosis. In patient 2 involved lymph node as well as spleen was available, and in patient 3 involved spleen before treatment and heavily involved lung tissue at autopsy could be studied. Patient data are summarized in Table 1.

DNA isolation and gene analyses. DNA was isolated from the selected tissue blocks. As controls for germ line patterns, human placentas were used that were representative for the reported restriction fragment polymorphism in the λ gene locus.¹⁹ Minced

Reactivity key: +, majority of Reed-Sternberg cells are positive; ±, minority of Reed-Sternberg cells are positive; —, Reed-Sternberg cells—negative.

tissues were incubated at 37°C overnight in 10 mmol/L Tris-HCl, pH 8.0, 100 mmol/L NaCl, and 1 mmol/L EDTA containing 1% (wt/vol) sodium dodecyl sulfate (SDS) and 100 µg proteinase K/mL buffer. High-molecular weight DNA was obtained after extractions with phenol, incubation with DNase-free RNase A, further extraction with phenol/chloroform (1:1, vol/vol), and precipitation at –20°C with 2 vol of ethanol and 1/10 vol of a 3-mol/L sodium acetate solution. Digestions were carried out with *Eco*RI or *Bam*HI in the buffers recommended by the supplier (Boehringer, Mannheim, Göttingen) at 37°C for three to four hours by using 2.5

U of enzyme/µg of DNA. Digestion products were separated by size on 0.6% agarose gels and transferred to nitrocellulose filters (Sartorius) by the method of Southern.²⁰ Filters were prehybridized and subsequently hybridized with a nick-translated ³²P-probe according to standard methods.²¹

The immunoglobulin gene probes, kindly provided by Dr P. Leder (Harvard Medical School), were human genomic DNA fragments specific for the κ constant region Hu κC–2.5-kB Ri-Ri,²² the λ constant region Hu λC2–5-kB (kilobase) *Hind*III,²³ and the heavy-chain joining region Hu J_H–*Bam* *Hind*III,²⁴ all subcloned in

Fig 1. H&E-stained tissue sections of cases 3, 4, and 5. Figure 1A shows involved spleen and 1B involved lung tissue at autopsy of case 3. Figure 1C shows the diagnostic lymph node and 1D the involved liver tissue at autopsy of case 4. Figure 1E shows the diagnostic lymph node and 1F the involved lung tissue at autopsy of patient 5. In all tissues typical Reed-Sternberg cells can be identified, and in Figs 1B, D, and F, Reed-Sternberg cells and their variants predominate. (Original magnification ×350.)

pBR322. The probe for the T cell receptor α chain was pY1.4 Jurkat cDNA containing V, D, J, and C sequences and cloned into the *EcoRI* site of pUc8.²⁵ The probe for the T cell receptor β chain was a 770-bp (base pairs) Jurkat cDNA containing J and C sequences and cloned into the *PstI* site of pBR322.^{17,26} Both probes were provided by Dr Tak W. Mak (Ontario Cancer Institute). After hybridization, the filters were washed according to the procedure of Maniatis et al²¹ and exposed to Kodak XAR5 film with intensifying screens at -80°C for various periods (one to five days).

Immunohistological procedures. Immunohistological stainings were performed according to standard procedures.²⁷ Anti-B cell antibodies B1, B2, and B4, anti-T cell antibodies OKT11 and OKT3, anti-Reed-Sternberg cell reagents Ki-1 and Leu M1, anti-transferrin receptor T9, anti-HLA-DR antibody OKI1, and anti-interleukin 2 receptor antibody Tac were used (Table 2). Five-micrometer frozen sections were fixed in acetone, incubated with optimal dilutions of the monoclonal antibodies for 30 minutes, washed in phosphate-buffered saline (PBS) for five minutes, and subsequently incubated with horseradish peroxidase-conjugated rabbit antimouse Ig antibodies (Dakopatts, Copenhagen) diluted 1:20 for 15 minutes. After another wash for five minutes, the peroxidase activity was demonstrated by staining with 3-amino-9-ethylcarbazole and H_2O_2 for ten minutes, which resulted in a red reaction product. The sections were counterstained with hemalum to identify the Reed-Sternberg cells.

RESULTS

The histological findings in the diagnostic lymph node sections and in the involved liver and lung tissues at autopsy of patients 3, 4, and 5 are illustrated in Fig 1. Reed-Sternberg cells and their variants were the predominating cell type in the selected tissues.

The results of the immunoglobulin gene analyses in the patients with clonal rearrangements are shown in Figs 2 to 4 and summarized in Table 3. The tissues of patients 6 to 11 had germ line patterns with all probes used. All experiments were repeated with constant results. The DNA of patient 2 was also treated with double amounts of enzymes to exclude the presence of undigested DNA. Figure 2 shows the results of the hybridization with the J_H probe after enzymatic digestion with *Bam*HI. In the placental controls the probe hybridized with a 19-kB fragment, which might thus be

Fig 2. Autoradiographs of hybridization with J_H probe. Germ lines are indicated by dashes. Rearranged bands, indicated by arrowheads, are present in lanes B, G, and H. Results are shown for digestion with *Bam*HI, except for lane F, which was *Eco*RI digested.

Fig 3. Autoradiographs of hybridization with κC probe. Germ lines are indicated by dashes. Rearranged bands, indicated by arrowheads, are present in lanes B, C, D, F, and H. In lane G the κC genes appear to be deleted. Results are shown for digestion with *Bam*HI.

considered to represent a germ line pattern. Rearranged bands were detected in lane B (lymph node patient 1), lane G (liver patient 4), and lane H (lung patient 5), and a germ line pattern was seen in lanes A, C, D, E, and F (placenta and patients 2 and 3). In some lanes an additional faint band can be observed below the germ line band. This band is also present in control placentas at longer exposure times. Hybridization with the J_H probe after enzymatic digestion with *Eco*RI gave rearrangements in the same samples as with *Bam*HI and, in addition, two rearranged bands in the lung tissue of patient 3. The rearrangements in lanes G and H, which appear similar after *Bam*HI enzymatic digestion, are clearly different from each other when *Eco*RI digestion is performed. Figure 3 shows the results obtained with the κC probe. Hybridizing 12-kB DNA fragments representing the germ line pattern were found in the placental controls. Rearranged bands were detected in lanes B (lymph node patient 1), F (lung patient 3), and H (lung patient 5), whereas the κC gene appears to be deleted in lane G (liver patient 4) where only a very faint germ line resulting from some normal admixed cells can be seen. Lanes C and D (lymph node and spleen of patient 2) showed faint rearranged bands, not present in normal liver tissue of this patient and, as mentioned previously, still present after

Fig 4. Autoradiographs of hybridization with $\lambda C2$ probe. Germ lines are indicated by dashes, which demonstrate the restriction fragment polymorphism of the λ gene locus. A rearranged band (indicated by an arrowhead) is present in lane G. Results are shown for digestion with *Eco*RI.

Table 3. Summary of Results in Tissues With Clonal Rearrangements of Ig Genes

Tissue	J _H	κC	λC2
Lymph node case 1	Rearranged	Rearranged	Germ line
Lymph node case 2	Germ line	Rearranged (faint)	Germ line
Spleen case 2	Germ line	Rearranged (faint)	Germ line
Spleen case 3	Germ line	Germ line	Germ line
Lung case 3	Rearranged (EcoRI)	Rearranged	Germ line
Liver case 4	Rearranged	Deleted	Rearranged
Lung case 5	Rearranged	Rearranged	Germ line

digestion with double amounts of enzyme. A germ line pattern was seen in lanes A (placenta) and E (spleen patient 3). Figure 4 shows the results obtained with the λC2 probe. Three different germ line patterns of hybridization with this probe were found in the placental controls. These patterns consisted of three fragments at 16 kB, 14 kB, and 8 kB; four fragments at 18 kB, 16 kB, 14 kB, and 8 kB; and three fragments at 18 kB, 16 kB, and 14 kB respectively. In addition, in some lanes faint bands were observed at 21- and at 5-kB positions. Rearranged bands were only detected in lane G (liver patient 5).

No rearrangements were found by using the TCR α probe, neither with *Bam*HI-digested DNA nor with *Eco*RI-digested DNA. Rearranged bands were also not detected in *Bam*HI-, *Eco*RI-, and *Hind*III-digested DNA by using the TCR β probe.

The results of the immunoperoxidase staining reactions in the cases with Ig gene rearrangements are summarized in Table 2. In all cases reactivity with anti-Reed-Sternberg cell antibody Ki-1 was observed. Leu M1 was reactive with all but one case (patient 4), generally with paranuclear cytoplasmic and membrane staining. B1 and B4 were reactive with the Reed-Sternberg cells in tissue sections of three patients, with variable proportions of positive cells and variable staining intensity. In one case (patient 3), several typical Reed-Sternberg cells showed membrane and cytoplasmic reactivity with B2 antibody. Generally, no reactivity of Reed-Sternberg cells was observed with anti-E rosette receptor antibody OKT11 and anti-T cell receptor antibody OKT3. However, in case 1 a few Reed-Sternberg cells with clearly positive OKT11 and OKT3 staining were observed, although the vast majority of Reed-Sternberg cells in this case were B1-positive. Staining with anti-Tac showed Reed-

Sternberg cells with cytoplasmic and also membrane staining of variable intensity (Fig 5). All Reed-Sternberg cells were strongly reactive with anti-transferrin receptor antibody OKT9 and anti-HLA-DR antibody OKI1. Cases 6 to 11 without detectable Ig gene rearrangements had similar immunophenotypes of the Reed-Sternberg cells as the positive cases.

DISCUSSION

The findings indicate the presence of clonal populations of cells possessing uniform rearrangements of immunoglobulin genes and the absence of clonal cell populations with rearrangements of T cell receptor genes. Similar results were obtained by Weiss et al in a number of cases with the recurrent nodular sclerosis type of Hodgkin's disease.³⁶ For an interpretation of the results, it should be kept in mind that Reed-Sternberg cells and their variants generally constitute only a minority of the cell population in tissue involved by Hodgkin's disease, the majority being T lymphocytes, macrophages, and eosinophils. Therefore, possible DNA rearrangements in minor clonal populations of Reed-Sternberg cells may stay below the threshold of sensitivity of the blotting technique. This may explain why in several lymph node samples only germ line configurations of the immunoglobulin and T cell receptor genes were observed, whereas in patients 1 and 2 only very faint rearranged bands were present. In addition, the possibility cannot be excluded that there are multiple clones of Reed-Sternberg cells in early Hodgkin's disease, each remaining below the threshold of sensitivity. The tissues obtained at autopsy showed a tumorous infiltration by Reed-Sternberg cells and only a minor admixture of other cell types, which explains the faintness or absence of germ lines in these samples. These tissues are representative for late stages of Hodgkin's disease when expansion of clonal populations may have occurred.

An unexpected finding, because it is not in agreement with the supposed sequence of heavy- and light-chain gene rearrangements, is the presence of a rearranged κ band in the lymph node and spleen of patient 2 without detectable heavy-chain rearrangement. A similar situation was observed in a patient with a lymphoproliferative disorder after cardiac transplantation.³⁷

However, since the sensitivity of the light-chain probes appears to be ten to 20 times higher than that of the J_H probe,³⁸ the rearranged population may have been too small to be detected in the J_H analysis. Alternatively, deletion of rearranged heavy-chain genes may have occurred. The faint

Fig 5. Immunohistological stainings of frozen tissue sections of the lymph node of patient 2 that demonstrate positive staining of Reed-Sternberg cells with Leu M1 (A), Tac (B), and Ki-1 (C). (Original magnification $\times 350$.)

extra 12-kB band observed in some lanes after hybridization with the J_H probe is also seen in all placental controls after longer exposure periods and has been described previously.³⁷ The faint extra 5-kB band observed in some lanes after hybridization with the $\lambda C2$ probe has previously been described as a $C\lambda$ pseudogene.¹⁹ The 21-kB band was found as a relatively unusual polymorphism by Hieter et al.²³ The importance of using different restriction enzymes (*Bam*HI and *Eco*RI) for DNA digestion and subsequent analysis with the J_H probe is exemplified by the absence of rearranged bands in patient 3 after *Bam*HI digestion and the presence of rearranged bands after *Eco*RI digestion. In addition, the rearrangements in cases 4 and 5, which appeared similar after *Bam*HI digestion, could be shown to be clearly different after *Eco*RI digestion.

The results of our study do not indicate which cell population within the tissue samples contained the clonal rearrangements. The presence of heavy-chain rearrangements has also been noted in myeloid and T cell neoplasms.^{39,40} So far light-chain rearrangements have been found exclusively in B cell neoplasms. Therefore it is likely that the rearranged immunoglobulin bands represent clonal B cell populations. The next question is whether these clonal B cell populations could be the Reed-Sternberg cells and their variants. Arguments in favor of this are the finding that clonal populations are found exclusively in cases with numerous Reed-Sternberg cells and not in cases with a predominance of small T or B lymphocytes and also that Reed-Sternberg cells in some cases express pan-B cell markers. However, in other cases Reed-Sternberg cells expressed no such B cell markers. Similar results were obtained in other studies.^{11,12} An alternative explanation could be the presence of a monoclonal population of B lymphocytes, benign or malignant, that could not be distinguished morphologically. This cannot be excluded in some of the cases in which significant numbers of

scattered B lymphocytes and reactive follicles are present. The absence of monoclonal immunoglobulin in the immunohistological stainings pleads against this possibility in our cases. Nevertheless, during this study we did exclude one case that had a composite lymphoma consisting of Hodgkin's disease and a lymphocytic lymphoma with plasmacytoid differentiation since the lymphocytes in this case clearly had monoclonal heavy- and light-chain immunoglobulin staining. In the autopsy cases the number of B lymphocytes as detected with antiimmunoglobulin reagents and pan-B cell antibodies was negligible, whereas the vast majority of the cells could be identified both morphologically and immunohistologically as Reed-Sternberg cells and variants. These arguments suggest that the clonal immunoglobulin gene rearrangements derive from Reed-Sternberg cells. This implies that the Reed-Sternberg cells in these cases are of B cell origin. However, to prove that Reed-Sternberg cells are B cells, it will be necessary to isolate these cells and demonstrate Ig gene rearrangements and Ig messenger RNA and to induce these cells to produce immunoglobulin since this appears to be the only absolute proof for the B cell character of cells. All other markers, including the gene rearrangements, can only provide strong arguments for the lineage of neoplastic cells.

ACKNOWLEDGMENT

We are indebted to Philip Leder, Department of Genetics, Harvard Medical School, who kindly provided the DNA probes for the κ and λ constant region and the heavy-chain joining region and Tak W. Mak (Ontario Cancer Institute) who provided the probes for the T cell receptor α and β chain. We also thank Lee Nadler, Dana Farber Institute, Harvard Medical School, for the gift of B1 and B2 antibodies; Harald Stein, Department of Pathology, Free University of Berlin for Ki-1 antibody; and Thomas Waldmann, National Cancer Institute, Bethesda, for Tac antibody.

Growth Factor Requirements of Childhood Acute Leukemia: Establishment of GM-CSF-Dependent Cell Lines

By Beverly Lange, Mauro Valtieri, Daniela Santoli, Daniele Caracciolo, Fulvio Mavilio, Ingrid Gemperlein, Constance Griffin, Beverly Emanuel, Janet Finan, Peter Nowell, and Giovanni Rovera

Eight permanent cell lines were established from cells of 50 consecutive patients with childhood acute leukemia. Three cell lines required growth factor-containing conditioned media. Analysis using blocking antisera and recombinant granulocytic macrophage (GM) colony-stimulating factor (CSF) identified GM-CSF as a growth factor required to establish the latter three cell lines and necessary for their continuous proliferation in chemically defined medium. Two of the GM-CSF-dependent cell lines were derived from patients with undifferentiated T- and a biphenotypic B-myelomonocytic leukemia, which suggests that GM-CSF might maintain proliferation of leukemias originating from

immature progenitor cells. Cytogenetic analysis indicated that all established leukemic cell lines were aneuploid, with six lines containing chromosomal alterations related to those observed in the leukemic cells of the patient. Two patients did not have an abnormal clone identified in the marrow but did yield an aneuploid cell line. These studies indicate that GM-CSF-dependent leukemic cell lines can be established in a fraction of childhood leukemia. These cell lines lend themselves to studies aimed at the evaluation in vitro of the role of growth factors in controlling proliferation and differentiation of leukemic cells.

© 1987 by Grune & Stratton, Inc.

HUMAN LEUKEMIC CELLS usually fail to proliferate autonomously in vitro.¹⁻³ The dependence of human leukemic cell proliferation on specific hematopoietic growth factors was first demonstrated in well-differentiated or partially differentiated human T leukemia cells that grow in media supplemented with interleukin-2 (IL2).⁴ However, highly undifferentiated leukemic T cells do not respond to IL2. The growth factors required to sustain proliferation in vitro of human acute myeloblastic leukemia (AML) and pre-B leukemia cells are not yet well defined. A small fraction of AML cells can form colonies in semisolid media supplemented with conditioned media (CM) containing colony-stimulating activity for normal myeloid cells.^{1,5,6} Recent work using recombinant granulocytic macrophage colony-stimulating factor (GM-CSF) has indicated that this growth factor can efficiently replace CM to sustain limited proliferation of leukemic cells.^{7,8} However, the leukemic colonies usually undergo terminal differentiation, and subculturing is not possible for more than two or three passages. The long-term suspension culture system for normal myeloid and erythroid precursor cells⁹ has proved to be inadequate for human leukemia cells since it tends to select for growth of normal rather than malignant clones.¹⁰ Long-term culture of AML using CM from phytohemagglutinin-stimulated lymphocytes¹¹ or from a bladder carcinoma cell¹² has been successful in sustaining the growth of leukemic cells in

suspension for several weeks, but growth factor-dependent AML lines have not been reported.

We have cultured 50 consecutive cases of acute childhood leukemia in standard media and serum and in the presence of medium conditioned by three cell lines (Mo-T, JLB-1, and 5637) known to release into the medium a variety of hematopoietic growth factors.¹³⁻¹⁹ These cultures were used to determine (a) the frequency of leukemias able to continuously proliferate in the presence or absence of CM and (b) the specific factors responsible for such proliferation.

MATERIALS AND METHODS

Leukemic cells. Blast cells were obtained from the marrow or peripheral blood of 50 consecutive children with acute leukemia at diagnosis or at the time of relapse. Cases were classified according to the French-American-British (FAB) system.²⁰ Cases were also classified by risk categories according to Children's Cancer Study Group criteria.²¹ The described work was approved by the Human Subject Committee of Children's Hospital of Philadelphia, and informed consent was obtained in every case.

Long-term culture conditions and preparation of CM. Long-term cultures were established by using minor modifications of the procedures described.^{8,11} Low-density ($d = 1.077$) mononuclear cells were separated on a Ficoll-Hypaque gradient,²² washed twice in phosphate-buffered saline, and resuspended at 10^6 cells/mL in Iscove's modified Dulbecco's medium (IMDM) (GIBCO, Grand Island, NY) and 20% fetal bovine serum (FBS) (Hyclone, Logan, Utah) alone or with 10% filtered supernatant fluid of one of three cell lines: Mo-T,¹³ JLB-1,¹⁵ or 5637.¹⁶ For preparation of CM cells of these lines were grown to 70% to 80% confluence and placed in chemically defined medium (IMDM supplemented with insulin [$10 \mu\text{g/mL}$] and transferrin [$10 \mu\text{g/mL}$]).²³ Serum-free CM was collected five days later. Leukemic cells were placed in 24-well cluster dishes (Costar 3424, Costar, Cambridge, MA) in 5% CO_2 at 37°C . Cultures were adjusted to 10^6 cells/mL and refed at weekly intervals.

Short-term proliferative assays and clonogenic assays. To determine the proliferative response of the leukemic cell lines in vitro in the presence of CM and growth factors, 5×10^4 cells were plated in microwells and after three days in culture labeled with $1 \mu\text{Ci/mL}$ of ^3H -thymidine for 18 hours. After harvesting the cells, radioactivity incorporated into the DNA was determined by liquid scintillation counting. The ability of leukemic cells to form colonies in the presence of growth factors (CFU-L) was determined by using a modification of the method of Buick et al²⁴ and plating 1×10^4 cells

0006-4971/87/7001-0029\$3.00/0

in 1% ultralow-gelling agarose (FMC, Rockland, ME) containing 10% CM and 20% FBS and scoring the resulting colonies after seven to ten days. Clones were obtained by picking up the colonies with a Pasteur pipette and expanding them in liquid cultures.

Phenotypic characterization of long-term cultures and cell lines. Cells were collected and concentrated on slides by cytocentrifugation (Shandon Southern Products, Sewickley, PA) and stained for PAS, Sudan black, myeloperoxidase, nonspecific esterase, chloroacetate esterase, and acid phosphatase using established methods.^{25,26}

Indirect immunofluorescence assays were performed as described²⁷ by using an Ortho Cytofluorograf 50HH (Ortho Diagnostic Systems, Inc, Westwood, MA). Epstein-Barr nuclear antigen (EBNA) fluorescence assay was carried out on fixed slides as described by Reedman and Klein.²⁸

Karyotypic analysis. Karyotypic analysis of overnight cultures and direct preparations of fresh samples obtained from patients, of established cell lines, and of cultures proliferating for longer than 8 weeks was performed by standard techniques.²⁹

DNA preparation, Southern and Northern blot analysis. High-molecular weight DNA was isolated from tissue culture cells by using sodium dodecyl sulfate-proteinase K digestion.³⁰ After restriction enzyme digestion, the DNA was blotted to nylon membranes (Zetabind AMF Cuno, Meriden, CT) and covalently bound to the membrane by UV irradiation.³¹ Blots were prehybridized and hybridized with oligo-labeled probes³² and washed according to established procedures. Blots were exposed to Kodak XAR film for 24 hours at -70°C .

Cytoplasmic RNA was prepared by following the procedure of Chirgwin et al.³³ Five to 10 μg were electrophoresed on formaldehyde-containing agarose gels.³⁴ The blotting and hybridization procedures were similar to those used for Southern blots.

Reagents and probes. Recombinant human (rh) GM-CSF, G-CSF, and anti-GM-CSF sheep antiserum were gifts of Dr Steven Clark (Genetics Institute, Boston). A plasmid containing the 3.3-kb germline *EcoRI-HindIII* μ fragment was a gift of P. Leder (Harvard University, Boston). Plasmids containing the 0.30-kb *MboII-HindI* fragment of the *Ck* gene and an 8.0-kb *EcoRI* fragment containing the *CX2* and *CX3* genes were gifts of T.H. Rabbitts (MRC Laboratory of Molecular Biology, Cambridge, UK).³⁵ The T cell receptor β -chain constant-region probe was the *HincII* 3' fragment of the human YTJ-2 cDNA clone and was provided by Dr T.W. Mak (University of Toronto).³⁶ A plasmid (pH 13) containing the 5' end of the human T-lymphotropic virus II (HTLV II)³⁷ was a gift of Dr D.W. Golde (UCLA, Los Angeles). A plasmid (B95-8 *EcoRI* C fragment) containing a 9.5-kb fragment of the Epstein-Barr virus (EBV) genome³⁸ was obtained from Dr N. Fraser (The Wistar Institute, Philadelphia).

Monoclonal antibodies T11, T10, T3, T6, B4, and M1 were purchased from Ortho Diagnostic Systems, Inc (Westwood, MA); Leu1, LeuM2 and LeuM3 from Becton Dickinson (Mountain View, CA); J5 and Ia from New England Nuclear (Boston); My3, -4, -7, and -9 from Coulter Immunology (Hialeah, FL); and 3A1 from the American Type Culture Collection (Rockville, MD). Monoclonal antibodies R1B19, S3.13, S4.7, and S16.144 were characterized in this laboratory and have been described.³⁹

RESULTS

Tables 1 to 3 summarize the characteristics of the 50 acute childhood leukemias included in this study. Thirty of these cases were classified as pre-B (Table 1), seven as T (Table 2), and 13 as AML leukemias (Table 3). Thirty-four cases were from untreated, newly diagnosed patients, 15 were in relapse, and one (patient 49) was a second malignant neoplasm in a

boy who had a marrow transplant for neuroblastoma. Among patients with pre-B acute lymphocytic leukemia (ALL), 3 were originally in the low-risk category, 21 were moderate risk, 4 were high risk, and 2 were not classified insofar as they had Sudan black-positive blasts with lymphoid morphology and a pre-B immunologic phenotype. Both had failed AML therapy. Among the T cell leukemias, six of eight were high risk, one was moderate risk, and one was a biphenotypic T cell monoblast with a predominance of T cell lymphoblasts. Cells from two patients had L2 morphology and 5 had L1 morphology. All AML patients are at high risk of relapse.

In the original chromosome studies on these 50 patients, a karyotypically abnormal clone replacing all or part of the bone marrow was found in 24 patients; only normal metaphases were found in 18 patients. Results were inconclusive in eight cases.

The percentage of blast cells in the marrow used for these studies ranged from more than 90% in the majority of cases to 28% in one case of pre-B ALL.

Establishment of cell lines. Of the 50 cases, cell lines growing for more than 1 year in culture were established from ten cases. Two of these cell lines (cases 20 and 39) consisted of EBV-transformed cells, as demonstrated by EBNA immunofluorescence and by Southern blotting with an EBV specific probe, and were discarded. The eight remaining cases were derived from three pre-B, two T, and two AML, one of which was eventually identified as a

Abbreviations: R, rearranged; D, deleted; G, germ line.

biphenotypic (B-myeloid) leukemia (see Table 4). None of the three pre-B lines required CM for growth. The cell line derived from case 35 (TALL-101) required CM from JLB-1 cells but grew almost as well in Mo-T and 5637 CM. The T cell line TALL-1 (from case 31) grew without CM. Among the AML lines, line AML-1 (from case 46) grew spontaneously, and AML-193 (from case 38) and MV4-11 (from case 50) grew equally well in Mo-T, JLB-1, or 5637 CM. In all cases, proliferation began during the first week in culture and continued at approximately the same rate thereafter.

Identification of GM-CSF as the growth factor required for maintenance and establishment of some cell lines. Multiple factors are present in the CM of HTLV-transformed T cells,¹³ and the media from the Mo-T cell line

Fig 1. Effect of G- and GM-CSF on thymidine incorporation of eight cell lines. Control cultures were maintained in IMDM supplemented with 20% FBS. Ordinate: stimulation index = cpm experimental/cpm of control cultures.

Fig 2. Effect of blocking antiserum against GM-CSF on three cell lines growing in CM.

have been used as the source for purification of GM-CSF.¹⁴ Three factors have been identified in the CM of 5637, ie, G-CSF,¹⁷ GM-CSF,¹⁸ and hemopoietin L,¹⁹ a factor shown to render cells competent for the effect of M-CSF. Since the three CM had approximately the same biological activity in stimulating leukemic cell cultures and all three cell lines produce GM-CSF, we investigated the role of GM-CSF in the establishment of the cell lines.

The five EBV-negative cell lines that established spontaneously and the three cell lines that required CM were screened for their proliferative response to recombinant growth factors. Thymidine incorporation was measured after addition of GM-CSF or G-CSF at varying concentrations to the cell lines growing in IMDM supplemented with 10% serum. Only the three lines that required CM for establishment proliferated in response to recombinant GM-CSF treatment (Fig 1). The addition of GM-CSF-specific blocking antiserum to cells growing in the media supplemented with the three CM reduced ³H-thymidine incorporation to levels observed in the absence of GM-CSF (Fig 2), thereby

Fig 3. Growth curve of TALL-101 (panel A), AML-193 (panel B), and MV4-11 (panel C) cells grown in chemically defined medium alone or supplemented with rhGM-CSF (10 ng/mL).

indicating that GM-CSF accounts for the stimulatory activity in the different CM.

To determine whether GM-CSF was sufficient to support the continuous proliferation of the cells in the absence of other factors in serum, the three cell lines were transferred to chemically defined medium and their growth in the presence or in the absence of GM-CSF compared (Fig 3). Two of the cell lines (AML-193 and TALL-101) clearly maintained their requirement for GM-CSF. MV4-11 cells were able to grow even in the absence of GM-CSF, but the proliferation rate was approximately 50% less than that of the same cells growing in GM-CSF. The frozen leukemic cells of the patient from which the MV4-11 cell line was derived were cloned in a CFU-L assay using medium only or medium supplemented with GM-CSF (10 ng/mL) (see Table 5). Colonies could be obtained only in plates containing GM-CSF. When the colonies were individually picked and replated, only a small fraction (4%) grew in culture, and again, they rapidly became independent of the requirement for GM-CSF.

To rule out autocrine production of growth factors as the mechanism controlling proliferation of the cell lines, the RNA of the eight cell lines was probed by Northern blot analysis using a GM-CSF and a G-CSF probe. No specific mRNA for such a growth factor could be detected (not shown).

Genotypic characterization. To determine whether lineage-specific gene rearrangement was present in the eight cell lines, their DNA was digested with several restriction enzymes and hybridized to recombinant DNA probes specific for the IgM heavy chain, κ and λ light chains loci, and for the T β cell receptor locus. Representative patterns of

†A total of 25 individual colonies were examined.

rearranged genes are shown in Fig 4. The three cell lines with a pre-B phenotype (ALL-1, ALL-2, and ALL-202) also had a pre-B genotype with rearrangement of $J\mu$ in the case of ALL-202, rearrangement of $J\mu$ and κ in the case of ALL-1 and rearrangement of $J\mu$ and deletion of both κ loci in the case of ALL-2 (Fig 4A and B). Of the two cell lines derived from patients with T leukemias, both had a T cell genotype showing a rearranged $T\beta$ gene. TALL-1 cells had a rearrangement in the $T\beta 1$ gene (Fig 4C) and actively transcribe $T\beta$ RNA (not shown), whereas TALL-101 showed a nonproductive rearrangement in the $T\beta 2$ locus.⁴⁰ Myeloid cell lines (AML-193, AML-1) showed a germ line configuration for all genes tested. MV4-11 cells with a t(4;11) translocation and clinically diagnosed as an AML have a rearranged κ light chain but not $J\mu$ (Fig 4B). Table 4 summarizes the genotype of the cell lines. Since three cell lines (AML-193, TALL-101, and MV4-11) were established with the CM of HTLV II-transformed cells, Southern blots were done with an HTLV II-specific probe; no hybridization was detected.

Phenotypic characterization. Table 6 compares the phenotype of the cell lines with those of the patients' leukemic cells. The morphological, histochemical, and immunologic phenotype of the cell lines were usually but not always identical to those of the patients' blast population present in vivo. For example, in the case of TALL-101 (case 35), the T11 marker was lost, and we were unable to demonstrate the presence of T lineage-specific markers.

Karyotype characterization. Six of the cell lines showed abnormal karyotypes related to those of the corresponding leukemic cells of the patient (Tables 1 to 3 and 7). In two cases (5 and 31) the derived cell lines were aneuploid, but only normal metaphases were observed in the patient's bone marrow. Cells of line ALL-1 have either one or two Philadelphia chromosomes resulting from the typical t(9;22) translocation. ALL-2 appears to have most of a chromosome 1q translocated to 19p. ALL-202 is missing a C-group chromosome and contains a small marker chromosome of undefined

origin. Both of the T-ALL lines carry translocations involving 8q24, the region of the *c-myc* locus, and TALL-1 (as well as ALL-2) also has a 6q- chromosome. The AML-193 line has an isochromosome 17q, and AML-1 has extra copies of chromosome 8. MV4-11 has the translocation t(4;11)(q21;q23), typically observed in biphenotypic congenital leukemias.^{41,42}

DISCUSSION

The present studies were done to determine the frequency of childhood leukemias able to continuously proliferate in standard or conditioned culture medium and to define the factors in CM responsible for proliferation.

We examined the proliferative response in vitro of 50 consecutive cases of acute leukemia at diagnosis or relapse. Of 50 cases, 13 (26%) were maintained in culture for more than 2 months, and their derivation from the leukemic cells was documented by chromosomal analysis. Among these, eight cases (16%) gave rise to permanent cell lines. Of these eight cases, five grew in medium supplemented with FBS, with no delay in growth, and three cases required GM-CSF for the establishment of the cultures. In the latter three cases, the original diagnosis was acute monocytic leukemia (AML-193), undifferentiated (TALL-101), and myelomonocytic leukemia (MV4-11), which later was modified to a B-myeloid leukemia with a typical t(4;11) translocation.

When grown in chemically defined medium, AML-193 and TALL-101 cells continued to require GM-CSF for growth. The effect of GM-CSF on the growth of early T and MV4-11 biphenotypic cells supports the concept that this factor acts on immature cells of several lineages.⁴³ It was recently shown that rhGM-CSF is effective in generating colonies of AML,⁸ but attempts to establish lines from the growing colonies have not been reported. Recently, Young and Griffin have reported AML cell lines that require GM-CSF and endogenously produce GM-CSF.⁴⁴ Under the culture conditions used, we have been unable to detect

Fig 4. Southern blot analysis of DNA from eight leukemic cell lines. High-molecular weight DNA was digested with *EcoRI* (panels A and C) or *BamHI* (panel B) and hybridized with Ig $J\mu$ probe (A) and κ (B), specific genomic fragments, and to a full length cDNA for the β chain of T cell receptor (C). Migration of λ *HindIII* fragments is shown as size markers (Kb). The Jurkat cell line DNA is shown as an additional control for a rearranged $T\beta$ locus.

production of GM-CSF by any of our cell lines either by Northern blot analysis or by bioassays of their conditioning media on human marrow cells in a colony-forming assay. Also, in the presence of GM-CSF, TALL-101 and AML-193 cells showed no density dependence within the range of cell densities (1 to 10×10^5) used in culture.

All of the established lines had an abnormal karyotype, and in several cases, this represented a further evolution of the chromosomal alterations originally observed in the patient. Four of the five lines with a lymphoid phenotype had karyotypic changes previously reported as occurring nonrandomly in lymphocytic neoplasms (ie, Philadelphia chromosome, translocations involving 8q24 and 19p13, a 6q chromosome). Similarly, the two myeloid lines had abnormalities commonly associated with nonlymphocytic leukemia (ie, $iso17q$, trisomy 8),⁴⁵ and the MV4-11 line has the $t(4;11)$ translocation that characterizes a subgroup of acute childhood leukemias.^{41,42} No diploid leukemic cell lines were established, and the question remains as to how often karyotypically normal metaphases from leukemic bone marrow represent the neoplastic population v residual nonneoplastic elements.⁴⁶ Interestingly, in our series, two patients who did

not have a chromosomally aberrant clone identified in the marrow did yield an aneuploid cell line.

From the relatively small number of cases in the present study, it is not possible to conclude whether cell lines with a specific chromosomal anomaly can be more readily established, either in the presence or the absence of growth factors. Current work is aimed at elucidating these relationships.

As previously discussed by Nara and McCulloch and Hoang and McCulloch,^{11,12} long-term cultures of leukemic cells may be more valuable than clonogenic assays in clinical studies. The relatively short clonogenic assays do not discriminate between cells with self-renewal ability and cells that proliferate and differentiate. The ability to maintain proliferating leukemic cells in culture should help determine the effects of long-term exposure to physiological or pharmacological agents that can potentially interfere with their growth in vivo. It may also permit the study of the development of resistance in the presence of relevant chemotherapeutic agents. All of the leukemic cell lines reported thus far are able to grow in medium supplemented with FBS, and no specific growth factor-dependent lines have been described. The GM-CSF-dependent lines TALL-101 and AML-193 and the GM-CSF-responsive cell line MV4-11 represent novel models to study in vitro the role of growth factors in supporting leukemic growth and to study the interaction of multiple growth factors on proliferation and differentiation of leukemic cells. Furthermore, the identification of factors that stimulate growth of leukemic cells would help to determine whether growth requirements of leukemic cells are different from those of normal myeloid progenitor cells. No spontaneous differentiation of the GM-CSF-dependent cells has been observed in culture. However, an increase of some lineage-specific markers was observed when TALL-101 were treated with interferon γ or tumor necrosis factor,⁴⁰ which

Table 7. Karyotype of Established Leukemic Cell Lines

No.	Cell Line	Karyotype
8	ALL-1	47, XX t(9;22)(q34;q11), + Ph
26	ALL-2	46, XX, -9, 6q-, 17p-, 12p+, der(19) t(1;19), + der(1) t(1;9)
5	ALL-202	46, XX, -C(79), + minute
31	TALL-1	46, XY, del(6)(q23), t(1;8)(q32;q24)
35	TALL-101	46, XY, t(8;14), (q24;q11), inv(9)
38	AML-193	46, XX, -17, +i(17q)

Recombinant Human Tumor Necrosis Factor α Regulates *c-myc* Expression in HL-60 Cells at the Level of Transcription

By A. Tobler, D. Johnston, and H.P. Koeffler

Recombinant human tumor necrosis factor α (TNF α) effectively inhibits clonal growth of leukemic cells from patients and several cell lines, including the promyelocytic HL-60 cells. Decreased expression of the *c-myc* oncogene is linked to growth arrest and terminal cellular differentiation. The present study characterizes the effect of TNF α on the regulation of the *c-myc* gene in HL-60 cells. TNF α (100 U/mL) rapidly inhibited messenger RNA (mRNA) accumulation of *c-myc* with a 50% reduction in <one hour. Dose-response studies showed that a 50% reduction of *c-myc* mRNA occurred in the range of 15 U/mL. In vitro nuclear run-on experiments showed that this decrease of *c-myc*-mRNA accumulation was the result of a reduced rate of transcription of *c-myc* by TNF α . Further studies demon-

strated that TNF α did not post-transcriptionally alter levels of *c-myc* mRNA, and the inhibitory action of TNF α on *c-myc* expression in HL-60 cells did not depend on new protein synthesis. In the conditions of all the experiments, TNF α did not affect cell viability. By contrast, TNF α (500 U/mL) did not decrease mRNA levels of *c-myc* in an HL-60 variant cell line whose growth was not inhibited by TNF α ; also TNF α (500 U/mL) increased *c-myc*-mRNA levels in normal fibroblasts whose growth is known to be stimulated by TNF α . These findings, in concert with prior studies, show a close association between growth inhibition of HL-60 cells and decreased levels of mRNA coding for *c-myc*.

RECOMBINANT human tumor necrosis factor α (TNF α) is a glycoprotein produced by myeloid cells. TNF α can potentially inhibit proliferation of leukemic cells from various human myeloid lines and from patients.¹ Part of the growth inhibitory action of TNF α on leukemic cells, including HL-60 promyelocytes, can be explained by induction of terminal differentiation.^{1,2} However, this cannot be the sole mechanism of growth inhibition because TNF α inhibits growth of cells from several myeloid lines that cannot be induced to differentiate by TNF α .¹ The gene product of *c-myc* is a nuclear protein³ linked to the control of normal cell proliferation and to neoplastic growth.^{4,7} The *c-myc* gene is amplified and transcribed at a high level in HL-60 cells.⁸⁻¹⁰ We show that TNF α rapidly and profoundly inhibits the expression of *c-myc* in HL-60 cells at the level of transcription, and this regulation occurs independently of new protein synthesis.

MATERIALS AND METHODS

Cell Culture

The promyelocytic leukemic cell line HL-60 was grown in alpha medium and 10% fetal calf serum (FCS) in a humidified atmosphere

with 7% CO₂. The TNF α (3.7×10^7 U/mg) was kept at 4°C and before use was diluted in alpha medium plus 10% FCS to the final concentrations. The TNF α -resistant HL-60 cell line was established by growing HL-60 cells in the presence of increasing concentrations of TNF α (1 to 50,000 U/mL) over a period of 6 months. Normal lung fibroblasts were obtained from a healthy volunteer, after informed consent was given, and were cultured in alpha medium and 10% FCS. The colony-forming assay in soft agar was performed as described.¹¹ Cell viability was determined in all experimental procedures by trypan blue exclusion.

RNA Isolation and RNA Blotting

Total RNA of HL-60 cells was extracted by the hot phenol method.¹² Cytoplasmic RNA of fibroblasts was isolated by phenol/chloroform extraction.¹³ RNA blotting was basically done as described.¹⁴ RNA samples were separated by a 1% agarose gel and transferred to a nylon-membrane filter. Blots were probed with [³²P]-oligolabeled (random primed) restriction fragments¹⁵ and hybridized for 16 to 24 hours at 42°C in 50% formamide, 2x SSC (1x = 150 mmol/L NaCl, 15 mmol/L sodium citrate), 5x Denhardt's, 0.1% sodium dodecyl sulfate (SDS), 10% dextran sulfate, and 100 μ g/mL salmon sperm. Filters were washed to a stringency of 0.1% SSC at 65°C and exposed to Kodak XAR film. Autoradiograms were developed at different exposures and scanned by densitometry.

DNA Probes

The *c-myc* DNA representing either exon II (Pst-Pst, 414 base pair [bp]) or exon III (ClaI-EcoRI, 1401 bp) were generated from the plasmid pHSRI.¹⁶ The β -actin DNA (EcoRI-BamHI, 700bp) was obtained from the pHF β A-3'ut plasmid,¹⁷ the heat shock DNA (BamHI-EcoRI, 800 bp) from the pUR-HS70 plasmid,¹⁸ and the β -globin DNA (BamHI, 1.8 kb) from the p β 4.4 plasmid.¹⁹

[¹⁴C]-Uridine Incorporation

HL-60 cells (1×10^6 /mL) were exposed to either TNF α or cycloheximide (CHX) in 24 well plates in quadruplicates per experimental point for four hours. For combined treatment, CHX was added 30 minutes before TNF α . The cells were pulsed with 0.5 μ Ci of [¹⁴C]-uridine for two hours at 37°C, washed twice in phosphate-buffered saline (PBS), precipitated in 5% trichloroacetic acid (TCA) for ten minutes, washed twice in 5% TCA, and heated at 80°C for 60 minutes. A total of 200 μ L of each sample was counted by liquid scintillation.

Nuclear Transcription

For run-on experiments nuclei were isolated by resuspending the cells in hypotonic buffer (10 mmol/L Tris-HCl [pH 7.4], 1 mmol/L KCl, 3 mmol/L MgCl₂) and lysing the cells with Nonidet P-40. The nuclei were washed twice in hypotonic buffer, resuspended in nuclear storage buffer (40% glycerol, 50 mmol/L Tris-HCl [pH 8.3], 5 mmol/L MgCl₂, 0.1 mmol/L EDTA) and stored at -70°C. Transcription of nuclei and RNA isolation were performed as described.²⁰ The nuclei (1×10^8) were thawed and incubated for 10 minutes at 26°C in reaction buffer containing 200 μ Ci [³²P]-UTP (3,000 Ci/mmol), and the labeled RNA was hybridized for three days to Southern blots of restriction-enzyme digests of the various clones.^{16,17,19} The blots were washed to a final stringency of $0.1 \times$ SSC, 0.1% SDS and washed again at room temperature for 30 minutes in RNase (10 μ g/mL, in 2x SSC). The filters were washed again at room temperature for 15 minutes in 2x SSC and exposed to Kodak XAR films.

RESULTS

Regulation of *c-myc*-Messenger RNA Accumulation by TNF α in HL-60 Cells

Time-response studies. HL-60 cells were exposed for various lengths of time (15 minutes to four hours) to TNF α (100 U/mL; Fig 1A). Total RNA was isolated and analyzed by Northern blot technique. The strongest band of hybridization was detected at 2.5 kilobase (kb) when a DNA probe representing Exon II of the *c-myc* gene was used. This is consistent with previously reported data. A second, smaller transcript was seen at 1.6 kb, as observed by other investigators.^{21,22} A four-hour exposure to TNF α (100 U/mL) reduced *c-myc* messenger RNA (mRNA) accumulation in HL-60 cells by 95%, and a 50% reduction occurred within <one hour (Fig 1A, upper panel). No change in viability of the cells occurred, as determined by trypan blue exclusion. Hybridization of the same blot with a β -actin DNA probe demonstrated no change in mRNA levels at each of the time points (Fig 1A, lower panel); and no change in mRNA levels was observed when the same blot was rehybridized with a heat shock cDNA probe¹⁸ (data not shown). This shows that TNF α does not nonspecifically alter mRNA turnover in HL-60 cells.

Dose-response studies. Exposure of HL-60 cells for four hours to various concentrations of TNF α (0.1 to 100 U/mL) revealed a dose-dependent decrease in *c-myc*-mRNA levels (Fig 1B); a 50% reduction occurred in the range of 15 U/mL. These results were similar whether the same Northern blot was hybridized with a DNA probe representing either exon II (upper panel) or exon III (lower panel) of the *c-myc* gene. No change in viability of the cells occurred, as determined by trypan blue exclusion.

Effect of TNF α on *c-myc* Expression in Different Cell Types

Several different experiments were performed to examine the effect of TNF α on *c-myc* expression in cells with different cell growth responses to TNF α . First, a variant cell line of HL-60, which is resistant to the growth inhibiting action of TNF α , was established. The growth inhibitory effect of TNF α was determined by the clonogenic assay in

Fig 1. Regulation of *c-myc*-mRNA levels by TNF α in HL-60 cells. (A) Time-response studies. Upper panel: Northern blot of total RNA (20 μ g/lane) from HL-60 cells hybridized with a *c-myc* DNA probe (Exon II); HL-60 cells were exposed for various times to TNF α (100 U/mL); lane 1, control (no TNF α); lane 2, 15-minutes exposure to TNF α ; lane 3, one-hour exposure; lane 4, four-hour exposure. Lower panel: Autoradiogram of hybridization of the same blot with β -actin. (B) Dose-response studies. Upper panel: Hybridization with a *c-myc* DNA probe (Exon II) to total HL-60 mRNA (20 μ g/lane) isolated after treatment for four hours with various concentrations of TNF α . Lane 1, control HL-60 cells; lane 2, HL-60 cells exposed to 0.1 U/mL TNF α ; lane 3, cells exposed to 1 U/mL; lane 4, 10 U/mL; lane 5, 100 U/mL. Lower panel: Hybridization of the same blot with a DNA probe of exon III of the *c-myc* gene. RNA analysis was performed as described in Materials and Methods.

soft agar.¹¹ When both the HL-60 variant and control cells were plated in the presence of TNF α (500 U/mL) in soft agar, no decrease in the colony numbers could be observed with the HL-60 variant cells, whereas a profound reduction in colony numbers occurred in HL-60 control cells (0% and

>99% reduction of colony formation respectively, as compared to the untreated control samples). Exposure of HL-60 variant cells to TNF α (100 or 500 U/mL) for four hours did not reduce *c-myc*-mRNA levels (Fig 2A). The viability of the cells before and after the experiments was >95% as determined by trypan blue exclusion.

Second, recent studies showed that TNF α enhances proliferation of normal fibroblasts from several tissues such as diploid skin (Detroit 551) and lung (WI-38) fibroblasts.²³ Normal human lung fibroblasts were exposed for one and four days to TNF α (500 U/mL), which resulted in an increase of *c-myc*-mRNA accumulation (2.7-fold increase as compared to fibroblasts not cultured with TNF α ; Fig 2B).

Influence of New Protein Synthesis on the Regulation of *c-myc* Expression by TNF α

To analyze the role of protein synthesis in the regulation of *c-myc*-mRNA accumulation by TNF α , the HL-60 cells were exposed for various lengths of time to either CHX 20 μ g/mL, a protein synthesis inhibitor; TNF α (100 U/mL); or TNF α in combination with CHX (Fig 3A). A short exposure (45 min) to CHX alone increased *c-myc*-mRNA levels by 2.5-fold (data not shown), which is in agreement with previously reported data.^{4,24,25} Pretreatment with CHX for 30 minutes and addition of TNF α for two hours resulted in a very profound decrease in *c-myc*-mRNA accumulation (>95% reduction compared with the untreated HL-60 controls) (Fig 3A, lane 4). CHX (2.5 hours, lane 2) and TNF α (two hours, lane 3) alone reduced *c-myc*-mRNA levels <10% and 90% respectively, compared with untreated HL-60. No *c-myc* mRNA was detectable even after a seven-day exposure of the autoradiogram when HL-60 cells were treated for four hours with TNF α in combination with a pre-exposure to CHX for

Fig 2. *c-myc*-mRNA accumulation in both a TNF α -resistant HL-60 variant cell line and normal lung fibroblasts after exposure to TNF α . (A) *c-myc*-mRNA levels in HL-60 variant cells, which are resistant to the cytotoxic effect of TNF α . Total RNA was isolated after a four-hour exposure of cells to TNF α at the concentrations of 100 U/mL (lane 2) and 500 U/mL (lane 3); lane 1 represents the total RNA from the untreated, TNF α -resistant HL-60 control cells. RNA was hybridized with [³²P]-labeled *c-myc* DNA (exon II) by Northern blotting. (B) Northern blot of normal lung fibroblasts exposed to TNF α . Cytoplasmic RNA was extracted after the cells were cultured with TNF α (500 U/mL) for one day (lane 3) and four days (lane 4). Lane 1, HL-60 RNA; lane 2, fibroblast RNA from the untreated control sample. Each lane in A and B contains 20 μ g RNA. Further analysis was performed as described in Materials and Methods.

Fig 3. Influence of the inhibition of protein synthesis on the action of TNF α in HL-60 cells. (A) *c-myc*-mRNA levels in HL-60 cells after treatment for various durations with TNF α (100 U/mL) and the protein synthesis inhibitor cycloheximide (CHX, 20 μ g/mL). Analysis was performed by blotting total RNA (20 μ g/lane) from HL-60 cells and hybridizing with a *c-myc* DNA probe (Exon II) as described in Materials and Methods. Lane 1, untreated control sample (no TNF α , no CHX); lanes 2, 5, RNA from HL-60 cells treated with CHX for 2.5 hours and 4.5 hours, respectively; lanes 3, 6, RNA isolated from HL-60 cells treated with TNF α (100 U/mL) for two hours and four hours, respectively; lanes 4, 7, RNA of the cells after treatment with CHX for an initial 30 minutes plus TNF α for an additional two hours and four hours, respectively. (B) [¹⁴C]-uridine incorporation by HL-60 cells after treatment with TNF α (100 U/mL) and CHX (20 μ g/mL) as a measurement of RNA metabolism. Analysis was performed as described in Materials and Methods. [¹⁴C]-uridine incorporation of: Bar 1, HL-60 control cells (no TNF α , no CHX); bar 2, HL-60 cells cultured for four hours with TNF α alone; bar 3, HL-60 cells cultured for four hours with CHX alone; bar 4, HL-60 cells treated with TNF α (four hours) plus CHX (4.5 hours). Results are expressed as relative incorporation (mean $\pm$ SD) as compared to the control HL-60 not treated with CHX or TNF α . Incorporation was measured in cpm; absolute values for the control samples were in the range of 0.957 to 1.236×10^6 cpm.

30 minutes (lane 7). CHX (4.5 hours, lane 5) and TNF α alone (4 hours, lane 6) decreased *c-myc* mRNA levels by 60% and 90% respectively. Control experiments using a β -actin DNA probe showed no changes in mRNA levels in HL-60 cells cultured in the presence of either CHX or TNF α alone (Fig 3A). However, a marked decrease in β -actin mRNA levels was observed in cells treated with both CHX and TNF α for two and four hours (lanes 4, 7). At each experimental point >97% of the cells were viable as determined by trypan blue exclusion.

A greater than 99% decrease of total RNA synthesis in HL-60 cells cultured for four hours with TNF α (100 U/mL) and CHX (20 μ g/mL) occurred compared with control cells, as measured by [¹⁴C]-uridine incorporation into trichloroacetic acid precipitable counts (Fig 3B). Exposure to CHX alone for four hours resulted in a 70% decrease of [¹⁴C]-uridine incorporation, whereas a slight increase (17%) was seen in these cells treated with TNF α alone for four hours. These results suggest that (1) new protein synthesis is

required for continued production of *c-myc* mRNA (Fig 3A, lanes 2, 5); (2) TNF α reduces steady-state *c-myc*-mRNA levels independently of new protein synthesis (Fig 3A, lanes 4, 7); (3) TNF α has a marked effect on general turnover of RNA in HL-60 cells when new protein synthesis is suppressed by CHX (Fig 3A, lanes 4, 7; Fig 3B, bar 4); and (4) the general transcriptional activity of HL-60 cells is not reduced by TNF α at the concentration tested (Fig 3B, bar 2), but the same concentration of TNF α has a profound effect on *c-myc*-mRNA level (Fig 3A, lanes 3, 6).

Mechanism of Control of *c-myc* Expression by TNF α

Decreased levels of *c-myc* mRNA in HL-60 cells exposed to TNF α could result from either a reduced rate of transcription or a destabilization of the *c-myc* mRNA (post-transcriptional regulation). The transcriptional regulation of *c-myc* expression by TNF α was studied by an in vitro transcriptional run-on assay. In this assay in vitro transcripts are generated by elongation of previously initiated RNA chains during incubation of isolated nuclei in the presence of [³²P]-UTP.²⁶ This measurement of in vitro chain elongation reflects the numbers of polymerase molecules actively involved in transcription before cell lysis. The run-on transcripts were hybridized to DNA immobilized on nylon-membrane filters. As shown in Fig 4A (lane 1), exposure of HL-60 cells to TNF α (100 U/mL) for four hours resulted in a profound decrease in the transcriptional rate of the *c-myc* (85% reduction as compared to untreated HL-60 cells). In the same experiments β -actin DNA (lane 2) was used as control. No decrease in β -actin transcripts was observed, demonstrating that comparable conditions were used for both experimental points. No hybridization could be detected to β -globin DNA (lane 3), showing that nonspecific hybridization did not occur to a DNA, whose gene expression is not detectable in HL-60 cells. The size separation of the respective *c-myc*, β -actin, and β -globin inserts from the vector DNA (4.4 kb) by gel electrophoresis further excludes a nonspecific hybridization to plasmid DNA. Viable cell counts did not change in the HL-60 cells exposed to TNF α (100 U/mL $\times$ 4 hours), as compared to control HL-60 cells.

Post-transcriptional regulation was studied by examining changes in *c-myc* mRNA at each time point of cell harvest. If TNF α mediated a post-transcriptional regulation of *c-myc*, the levels of *c-myc* mRNA would be lower in the TNF α plus actinomycin D-treated cells as compared with cells treated with actinomycin D alone. Actinomycin D blocked >98% of all transcription in HL-60 cells as determined by [¹⁴C]-uridine incorporation. As shown in Fig 4B, no change in *c-myc*-mRNA levels was detectable in HL-60 cells treated with TNF α plus actinomycin D as compared to cells treated with actinomycin D alone. Therefore TNF α probably has no effect on the stability of *c-myc* mRNA in HL-60 cells.

DISCUSSION

Both transcriptional and post-transcriptional mechanisms regulate *c-myc*-mRNA levels in human cells. A post-transcriptional regulation accounted for the decreased

Fig 4. (A) Transcriptional analysis of *c-myc* in isolated nuclei of HL-60 cells untreated or treated with TNF α (100 U/mL) for four hours. Analysis was performed as described in Materials and Methods. Autoradiograms show hybridization of [³²P]-labeled transcripts to the *c-myc* DNA (Exon II; lane 1). β -actin (lane 2) and β -globin (lane 3) were used as positive and negative controls respectively. The DNA inserts were size separated from their plasmid vectors by a 1.2% agarose gel and transferred to a nylon-membrane filter. (B) *c-myc*-mRNA accumulation in HL-60 cells after treatment with TNF α (100 U/mL) and actinomycin D (5 μ g/mL) for 75 minutes. Analysis was performed by RNA blotting as described in Materials and Methods. Total RNA (20 μ g/lane) was hybridized with a probe of *c-myc* DNA (Exon II). RNA from: lane 1, untreated HL-60 cells; lane 2, HL-60 cultured with TNF α ; lane 3, HL-60 cultured with actinomycin D; lane 4, HL-60 cultured with TNF α plus actinomycin D. The lower panel shows an autoradiogram of control hybridization of the same blot with β -actin.

c-myc-mRNA accumulation both in lymphoblasts treated with gamma-interferon^{27,28} and in F9 embryonal carcinoma cells induced to differentiate with chemicals.^{29,30} By contrast, a block to elongation of *c-myc* mRNA was shown to be responsible for the reduced transcription in HL-60 cells induced to differentiate with all-*trans*-retinoic acid.²¹ We demonstrated in the present paper that TNF α rapidly and sensitively inhibited the expression of the *c-myc* gene at the level of transcription in HL-60 cells (Figs 1A, 1B, 4A and 4B). By contrast, rate of transcription of β -actin remained unchanged, and the overall viability of HL-60 was not affected by TNF α . We also showed by using [¹⁴C]-uridine incorporation as a measurement of total RNA metabolism that TNF α did not decrease the overall transcriptional activity of HL-60 cells in the conditions that we employed (100 U/mL $\times$ four hours; Fig 3B); in fact, TNF α slightly stimulated [¹⁴C]-uridine incorporation. These results indicate that TNF α does not decrease nonspecifically the general transcriptional rate of HL-60 cells.

The TNF α produced a half-maximal inhibition of *c-myc* expression in the range of 15 U/mL after a four-hour

exposure to TNF α (Fig 1B). We recently showed that TNF α sensitively inhibited clonal growth of HL-60 cells in soft agar; and a 50% inhibition (ED₅₀) of clonal growth occurred in the range of 6 U/mL.¹ In this assay the cells were exposed for ten days to TNF α . Pulse-exposure experiments demonstrated that a three-hour exposure to 20 U/mL TNF α resulted in a 50% inhibition of HL-60 clonal growth. This nearly parallels the decrease in *c-myc*-mRNA levels in HL-60 cells (Figs 1A, 1B).

Our study using the TNF α -resistant HL-60 variant cell line demonstrated that TNF α does not decrease *c-myc*-mRNA levels in cells that are resistant to the growth-inhibiting action of TNF α (Fig 2A); and with normal lung fibroblasts, whose growth is enhanced by TNF α , the monokine actually increased the expression of *c-myc* mRNA (Fig 2B). Thus our results suggest an inverse association between growth inhibition mediated by TNF α and levels of *c-myc* mRNA in these cells.

The recent literature provides some controversial data about the effect of TNF α on HL-60 cells. Using early passages (15 to 20) of HL-60 cells, we found that TNF α very sensitively inhibited clonal growth of HL-60 cells in soft agar,¹ and in the present paper we demonstrate that TNF α reduces *c-myc* transcription in these cells in a parallel manner. By contrast, Peetre et al³¹ recently reported that wild-type HL-60 cells were highly resistant to the growth inhibition by TNF α in soft agar. However, a subclone of HL-60 cells was very sensitive to the inhibitory action of TNF α in the same assay. These discrepancies in the effects of TNF α on HL-60 cells might be more apparent than real and may result from the utilization of different sublines and passages of HL-60 cells or different TNF α preparations.

Furthermore we found that the action of TNF α on *c-myc* is not dependent on new protein synthesis (Figs 3A, 3B). Blockade of protein synthesis in HL-60 by CHX and treatment of the cells with TNF α resulted in a further decrease of *c-myc*-mRNA levels, compared with the levels in cells treated with either CHX or TNF α alone. In addition, TNF α

plus CHX markedly reduced steady-state mRNA levels of β -actin, while both TNF α and CHX alone had no effect on β -actin mRNA levels (Figs 3A). These results suggest that TNF α and CHX interact in a synergistic fashion, and in the absence of new protein synthesis, TNF α profoundly affects overall steady-state mRNA in HL-60 cells.

The mechanism by which TNF α exerts its growth-inhibiting activity is unknown. TNF α interacts with the cell through a single class of specific TNF α receptors.³²⁻³⁷ The means by which receptor-bound TNF is toxic to the cell is unclear. Experiments with inhibitors of TNF α suggest that internalization of the TNF α -receptor complex may be critical for its effect.³⁸ One possibility might be that, similar to the glucocorticoids, the TNF α -receptor complex specifically binds to certain DNA sequences in the region of *c-myc* and inhibits the transcription of the gene. Another possibility is that the TNF α -TNF α receptor complex activates a second messenger that directly or indirectly affects transcription of *c-myc*. Recent studies showed that the *c-myc* protein may be part of the DNA polymerase complex and is necessary for DNA synthesis in HL-60 cells.³⁹ TNF α , by inhibiting the transcription of *c-myc*, causes a decrease of *c-myc* protein levels, which in turn might contribute to the reduced proliferation and survival of HL-60 cells and neoplastic cells in general. Yet further studies are necessary to determine whether down-regulation of *c-myc* is a major cause of the growth inhibition of TNF α or is a secondary phenomenon.

ACKNOWLEDGMENT

We would like to thank Suzanne Bookstaver and Regina Simon for their excellent secretarial help; Carl Miller for helpful discussions; and Michael Shepard (Genentech, San Francisco) for providing recombinant TNF.

NOTE ADDED IN PROOF

After submission of this paper, Krönke et al also reported a transcriptional regulation of *c-myc* by HL-60 cells.⁴⁰

Recombinant Human GM-CSF Induces Leukocytosis and Activates Peripheral Blood Polymorphonuclear Neutrophils in Nonhuman Primates

By P. Mayer, C. Lam, H. Obenaus, E. Liehl, and J. Besemer

The *in vivo* efficacy of glycosylated and nonglycosylated recombinant human granulocyte macrophage colony-stimulating factor (rh GM-CSF) expressed in Chinese hamster ovary cells and *Escherichia coli* respectively was studied in rhesus monkeys following a daily subcutaneous (SC; three times) or intravenous (IV; over six hours) dose for seven consecutive days. The monkeys responded to the rh GM-CSF with a prompt (within 24 hours) rise in circulating white blood cells (WBCs). Thereafter the total cell counts increased steadily in a dose-dependent manner with repeated dosing to numbers six times over the pretreatment levels. Overall, granulocyte counts increased fivefold, lymphocytes twofold to fourfold, and monocytes threefold to fourfold. Platelets and erythrocytes were unaffected.

THE *IN VITRO* proliferation, differentiation, and functional activation of hematopoietic progenitor cells is dependent on the presence of a family of glycoproteins known as colony stimulating factors (CSFs).^{1,2} These factors are classified according to the types of hematopoietic progenitor cells with which they interact. GM-CSF stimulates the growth and differentiation of granulocyte and macrophage precursors, while G-CSF stimulates the terminal differentiation of granulocyte precursors, and M-CSF is thought to be responsible for the growth and differentiation of macrophage progenitors. The molecular biology and function of CSFs have been reviewed recently.¹

The molecular cloning of the complementary DNA (cDNA) for human GM-CSF has made it possible to determine the biological activities of the purified recombinant material in *in vitro* and *in vivo* test systems.^{3,5} The recombinant human GM-CSF (rh GM-CSF) stimulates the formation of macrophage, granulocyte, and eosinophil colonies in human bone marrow cell cultures.⁶ It also increases erythroid and multipotential colony formation in enriched human bone marrow and peripheral blood progenitor cell cultures containing erythropoietin.⁷⁻¹⁰ In addition, rh GM-CSF was able to prime mature human granulocytes for increased phagocytosis and eosinophils for elevated autofluorescence.^{3,9,11} Rh GM-CSF had no proliferative effects on murine hematopoietic cells³ but regulates the formation of granulocyte, macrophage, erythroid, and mixed colonies in nonhuman-primate bone marrow cultures.¹² This suggests that the *in vivo* activity of rh GM-CSF can be evaluated in nonhuman primates. Recently it was reported that continuous infusion

Within 1 week after the end of treatment the leukocytosis had disappeared. Of the two routes of treatment, SC (three times daily)-administered rh GM-CSF was more effective than the same dose given by a six-hour IV infusion. In addition to inducing leukocytosis, parenterally administered rh GM-CSF primed mature circulating granulocytes for enhanced oxidative metabolism and killing of an *E coli* strain. These results show that exogenously administered glycosylated or nonglycosylated rh GM-CSF is both an effective stimulator of leukocytosis and a potent activator of the phagocytic function of mature granulocytes in monkeys.

© 1987 by Grune & Stratton, Inc.

of a highly glycosylated form of the rh GM-CSF in monkeys elicited a dramatic leukocytosis.¹² The rh GM-CSF used in this primate study was expressed in genetically engineered Chinese hamster ovary (CHO) cells and had a similar degree of glycosylation as the natural product.

The purposes of the present study were: (1) to confirm the reported *in vivo* efficacy of the glycosylated rh GM-CSF by a route of administration other than continuous infusion; (2) to determine if nonglycosylated material is also active *in vivo*; and (3) to establish whether or not peripheral neutrophils become activated following *in vivo* administration of rh GM-CSF.

MATERIAL AND METHODS

Animals

Nine male and five female adult rhesus monkeys (*Macaca mulatta*) approximately 4- to 8-years old and weighing between 5 and 13 kg were kept individually in monkey cages in an air-conditioned room at 25°C. The animals were fed with certified primate pellets. The animals selected for the intravenous (IV) infusion studies were trained to sit in restraining chairs prior to the experiment.

Sources of rh GM-CSF

The glycosylated rh GM-CSF was purified from transfected CHO cells, as described elsewhere,^{3,4} and was provided by Genetics Institute, Cambridge, MA. The purity of the material, determined by Coomassie blue staining after digestion with N-glycanase, was 96.9%. It had a specific *in vitro* biological activity of 2×10^6 U/mg protein when assayed by thymidine incorporation by human peripheral blood myeloblast (CML) cells,¹³ and 1 to 2×10^5 U/mg protein when measured with a radioreceptor binding assay (manuscript in preparation). The nonglycosylated rh GM-CSF was extracted from *Escherichia coli* cells expressing the GM-CSF cDNA from a plasmid vector. The protein was accumulated intracellularly. *E coli*-derived rh GM-CSF was purified to homogeneity by a series of chromatographic steps, including high-performance liquid chromatography (HPLC), and had a specific activity of 2 to 4×10^7 U/mg protein in the CML bioassay and 5 to 10×10^5 U/mg protein in the radioreceptor assay (manuscript in preparation). The purity of this material was 99%, determined by HPLC analysis.

Endotoxic activity was determined in the rh GM-CSF preparation using a chromogenic *Limulus* amoebocyte lysate reagent kit (Whittaker, M.A., Bioproducts, Inc, Walkersville, MD).

Administration of rh GM-CSF to Monkeys

The IV infusion solutions were prepared by injecting the appropriate amount of the sterile filtered rh GM-CSF into infusion bags containing nonpyrogenic saline solution (Natrium chloratum physioli; Flex Flac, Leavosan, Austria). The infusion bags were prepared individually for each IV-treated monkey and contained 25 mL saline/kg body weight. To avoid nonspecific binding of rh GM-CSF to the plastic surfaces of the infusion devices, monkey serum at a concentration of 0.5% was added. The solutions were administered for seven consecutive days over a period of six hours and at a flow rate of approximately 1 mL/min.

The rh GM-CSF solution for the subcutaneous (SC) treatments was prepared by diluting the daily dose with nonpyrogenic saline containing 0.5% monkey serum to 15 mL. Five milliliters of the rh GM-CSF solution was administered SC at different sites in the back at 8 AM, 1 AM, and 6 PM each. The administrations were performed over a period of seven days.

The control monkeys received IV infusions or SC injections of nonpyrogenic saline with 0.5% monkey serum containing the same amount of endotoxin (LPS World Health Organization standard from *E. coli* J5) detected in the high dose of the rh GM-CSF preparation.

Hematologic Examinations

Blood was collected for hematologic examinations in EDTA-coated tubes during the pretreatment week on days -8 and -6. During the treatment period blood samples were collected every day prior to the infusions or SC injections (day 0 to day +6). In the post-treatment period blood was sampled three times a week for 3 weeks.

The hematologic examinations included the total counts of red blood cells (RBCs) and white blood cells (WBCs), determination of hemoglobin and hematocrit (Microcell counter CC 108, TOA; Tokyo, Japan) of platelets (Platelet counter PL 100, TOA; Tokyo, Japan) and reticulocytes (Brilliant cresyl blue staining), and differential blood count (Wright's stain).

Assay of Peripheral Blood Polymorphonuclear Neutrophil (PMN) Functions

PMNs were fractionated from heparinized venous blood by Ficoll-Hypaque gradient centrifugation and dextran sedimentation (99% pure and viable as evaluated by Giemsa stain and Trypan exclusion test). Superoxide anion generation was measured in response to the bacterial chemoattractant *N*-formyl-methionyl-leucyl-phenylalanine (f-MLP).¹¹ Briefly 5×10^6 polymorphonuclear cells (PMNs) suspended in 0.2 mL Hanks' balanced salt solution (HBSS) were added to each of two tubes containing 1.2 mg cytochrome C per mL. Superoxide dismutase was added to one tube, and f-MLP was added to both tubes at a final concentration of 10^{-8} mol/L. The cell suspensions were incubated at 37°C for 15 minutes, and superoxide dismutase inhibitable cytochrome C reduction was measured in a spectrophotometer at 550 nm (Ultrospec 4050 LKB, Sweden). The data were expressed as percent increase in the amount of O_2^- released by PMNs from monkeys during and after treatment with rh GM-CSF compared to values obtained from cells collected before treatment.

The bactericidal activity of PMNs was determined in whole blood by adding *E. coli* Δ 1060 to heparinized blood to give a bacteria-neutrophil ratio of 1. The mixture was shaken in a water bath at 37°C for two hours. After lysing the blood cells with 0.1% Triton X-100, the surviving organisms were estimated by plating various dilutions of the homogenates on Trypticase soy agar plates, incubating at 37°C for 24 hours, and counting the colony-forming units

(CFUs). The survival of the organisms in pooled fresh monkey serum was also evaluated in parallel.

Morphologic Examination of Bone Marrow Aspirates

Bone marrow samples were obtained by aspiration from the posterior ilial crest under general anesthesia (Ketalar, 20 mg/kg intramuscularly [IM]) prior to treatment and during the drug treatment period. Bone marrow smears were prepared and stained according to Pappenheim.^{13a} Differential cell count was performed by examining 200 white cells. In addition, the red cells were also recorded. The number of white and red cells was calculated in percent.

RESULTS

IV Infused Glycosylated rh GM-CSF-Induced Leukocytosis

Daily IV infusion of 253, 84, and 28 μ g glycoprotein rh GM-CSF per kilogram body weight in monkeys over seven days induced a prompt rise in total WBC counts in circula-

NOTE. Monkeys were treated daily either SC or by IV infusion with various doses of glycosylated or nonglycosylated GM-CSF over a period of seven consecutive days. Blood was collected daily, and WBC and differential counts were performed. Maximum WBC levels were reached on the last day of the treatment period or the day after.

tion (Fig 1 A to C). The leukocytosis appeared within 24 hours of the first infusion and increased steadily, with repeated dosing reaching maximum levels on the last day or one day after the termination of the treatment. The rise in WBC counts was dependent on the dose of the infused rh GM-CSF. In Table 1 the maximum levels of WBC counts of the monkeys infused with the various amounts of rh GM-CSF are listed. Even with the low dose of 28 μg glycoprotein/kg/d, a twofold increase in the maximum WBC count over the values of control animals could be observed. With the higher doses of 84 μg and 253 μg glycoprotein/kg/d, a threefold to fourfold increase in WBC compared to control animals was achieved. The infusion of 84 μg glycoprotein/kg/d seems to be sufficient to reach plateau levels of the WBC increase. WBC counts began to decline on the first or second day after termination of treatments and had returned to control levels almost within a week. The period for recovery to normal WBC levels was not dose dependent. The control monkeys infused with saline containing the small amount of endotoxin determined in the high dose did not show a response in their WBC counts.

Effect of Glycosylated and Nonglycosylated rh GM-CSF on Leukocyte Counts After Subcutaneous Injections

Subcutaneously injected rh GM-CSF was more effective in eliciting leukocytosis than the same dose infused IV. Representative results shown in Table 1 indicate that a daily SC dose of 84 μg glycoprotein/kg produced WBC counts two times higher than that elicited by an IV infusion with the same dose. The rise in WBC counts in response to SC treatments appeared within 24 hours of the start of the

treatments and amounted to a twofold to threefold increase in circulating WBC counts over the preinfusion counts. Thereafter the WBC counts increased steadily, with repeated dosing up to the last day of treatment. As observed with IV infusions, the elevated WBC counts fall to preinfusion levels within four to six days after termination of the treatments (Fig 2A).

Thus the WBC counts in monkeys that received SC either the glycosylated or the nonglycosylated rh GM-CSF peaked at 62×10^3 and 53×10^3 per μL blood respectively (Figs 2A and 2B). Since 84 μg of the glycosylated material had a protein content of 50 μg , it can be concluded that the protein moiety is the biologically active part. An increase in the daily dose of the nonglycosylated material to 150 μg protein/kg or a decrease to a daily dose of 15 $\mu\text{g}/\text{kg}$ did not change the peak WBC levels significantly. Yet decreasing the daily dose to 5 μg protein/kg resulted in maximum WBC levels of 31×10^3 for the nonglycosylated and 32×10^3 for the glycosylated rh GM-CSF. A dose of 1.7 μg protein/kg elicited maximum WBC counts of 26×10^3 for the nonglycosylated form and 19×10^3 for the glycosylated material (Table 1). No clinical signs of toxicity were observed either in the IV-treated or in the SC-administered monkeys.

Again the small amounts of endotoxin detected in the high dose of rh GM-CSF and injected SC did not alter the WBC counts in control monkeys.

Effect of rh GM-CSF Treatment on Differential WBC Counts

Differential cell counts revealed that the increase in WBC counts was mainly due to the rise in segmented neutrophil

Fig 2. Changes in peripheral WBC levels in rhesus monkeys injected SC with glycosylated and nonglycosylated recombinant human GM-CSF (rh GM-CSF) for seven days (*). Filled symbols: Monkeys treated daily with 84 μ g/kg glycoprotein (A) or 50 μ g/kg protein (B). The daily dose was divided into three applications. Open symbols: Control animals injected with saline containing 7×10^{-9} mg endotoxin/kg.

numbers. The increase of segmented neutrophils paralleled the increase of the total WBC counts. The neutrophilia reached maximum levels on the last day of treatment with levels returning to normal values by days 2 to 5 after the termination of the treatments (Fig 3). Representative results in Table 1 show that the IV infusion of the low dose produced a more than twofold increase in neutrophil numbers compared to counts of the control monkeys. A threefold increase was observed in animals treated with the middle dose. The high-dose treatment did not increase the neutrophil counts further. The maximum neutrophil levels after SC treatments with the middle dose were twice as high as after IV infusions of the same dose (22.0 and 23.3 v 45.5 and 48.1 $\times 10^3$ neutrophils/ μ L blood). Therefore the three-times-daily SC administration of rh GM-CSF was more effective in increasing the neutrophil count than daily six-hour IV infusions.

Also a dose-dependent increase in the number of band cells was found. The increase and decline of band cell numbers showed a similar pattern as that of the segmented neutrophils. The most prominent increase in band cell levels was found in the SC-treated monkeys with a sevenfold to tenfold increase over control values (Fig 3).

Fig 3. Changes in peripheral neutrophil counts in rhesus monkeys injected SC with glycosylated recombinant human GM-CSF (rh GM-CSF) for seven days (*). Filled symbols: Monkeys treated with a daily dose of 84 μ g glycoprotein/kg. The daily dose was divided into three applications. Open symbols: Control animals injected with saline containing 7×10^{-9} mg endotoxin/kg. (A), Segmented neutrophils; (B), band cells.

Effect of rh GM-CSF Treatment on Monocyte Count

Blood monocyte levels were also elevated in response to the rh GM-CSF treatment. In the IV-treated monkeys this increase seems to be dose dependent. Maximum monocyte levels were exhibited in monkeys treated with the middle and high dose. The highest monocyte levels developed in monkeys treated by the SC route (Fig 4).

Effect of rh GM-CSF Treatment on Eosinophil Count

In all the monkeys an eosinophilia developed in response to rh GM-CSF. The rise in eosinophil counts was delayed when compared to the prompt onset of neutrophilia in response to rh GM-CSF treatment. Nevertheless maximum eosinophil numbers coincided with the last day of the treatment period (Fig 4). When the maximum eosinophil levels were compared, the variation between animals treated with the same dose was more than twofold. Nevertheless it seems that in the IV-treated monkeys the maximum increase in eosinophil numbers was also dose dependent (Table 1).

Effect of rh GM-CSF Treatment on Lymphocyte Count

An increase in the lymphocyte count (twofold to threefold) was seen in the high-dose IV-treated monkeys but not in the

Fig 4. Changes in peripheral blood levels of (A) monocytes, (B) eosinophils, and (C) lymphocytes in rhesus monkeys injected SC with glycosylated recombinant human GM-CSF. Filled symbols: Monkeys treated with a daily dose of 84 $\mu\text{g/kg}$ glycosylated rh GM-CSF. The daily dose was divided into three applications. Open symbols: Control animals injected with saline containing 7×10^{-9} mg endotoxin/kg.

middle- and low-dose infused animals (Table 1). A lymphocytosis of the same magnitude was exhibited in the monkeys treated SC with the middle dose (Fig 4). Monkeys treated SC with increasing doses of the nonglycosylated material seem to respond with a dose-dependent lymphocytosis. The maximum lymphocyte counts were determined in the monkey treated with the high dose of 150 $\mu\text{g/kg/d}$ SC (Table 1).

The control animals that received IV infusions or SC injections containing an equal amount of endotoxin as the high dose monkeys did not show any of the changes in the lymphocyte count mentioned above.

Effect of rh GM-CSF Treatment on RBCs and Platelets

In all monkeys a slight decrease in RBC count, in the hemoglobin values, and in hematocrit were observed. This decrease coincided with the beginning of the treatment period, showed its nadir (10% to 20% reduction) in the first week of the post-treatment period, and had a tendency to recover at the end of the third week of the post-treatment observation period. With this decrease in these red blood parameters, a concomitant increase in reticulocyte numbers (twofold to threefold) was observed. These changes were found in control animals and can be interpreted as a slight anemia due to the repeated sampling of larger volumes of blood throughout the study. No changes were found in the platelet counts during and also after the treatment with rh GM-CSF in monkeys.

Morphological Examination of Bone Marrow of Monkeys Treated With rh GM-CSF

Bone marrow was aspirated before treatment, on the third day of the seven-day treatment period and again one day after termination of treatments. The morphological examination of the smears revealed that there was no difference in the percentage of neutrophils, eosinophils, lymphocytes, and monocytes between treated and control animals. Even in the SC-treated monkeys that showed a threefold increase in peripheral neutrophil numbers on the third day of treatment and a fivefold increase one day after termination of the applications, no changes in the percentage of neutrophils were found during and after rh GM-CSF treatment compared to bone marrow smears taken before treatment. Also no changes were found in the granulocyte precursors and also in cells of the erythroid lineage.

Effect of rh GM-CSF Treatment on PMN Function

Generation of superoxide anion. Since rh GM-CSF readily primes mature neutrophils *in vitro* for enhanced metabolism on exposure to a soluble stimulus, it is reasonable to expect that the first detectable parameter of *in vivo* efficacy would be the appearance of a population of neutrophils in the circulation with increased oxidative metabolism. To support this view, blood samples were collected immediately before and after rh GM-CSF infusion on the first and third days and two days after the seven-day infusion period and again on day 14 of the post-treatment period. The generation of superoxide anion by purified neutrophils was induced with 10^{-8} mol/L f-MLP and measured as superoxide dismutase inhibitable reduction of cytochrome C. As shown in Fig 5A, the rh GM-CSF treatment readily primed neutrophils *in vivo* for enhanced superoxide anion (O_2^-) release, with maximum effect occurring after the third infusion of the seven-day treatment period. The high rh GM-CSF dose did not produce a higher O_2^- release from the neutrophils than the middle dose. The GM-CSF-mediated enhancement of O_2^- release was maintained throughout the infusion period. The neutrophils obtained from control monkey were not primed for enhanced O_2^- release. It was also of interest to note that rh GM-CSF administered SC significantly improved the oxidative metabolism of the neutrophils.

Killing of *E. coli*

To evaluate whether the enhanced generation of O_2^- by the neutrophils observed also lead to increased killing of *E. coli*, the survival of the bacteria in blood from rh GM-CSF treated and untreated monkeys was studied. The results (Fig 5B) show that the killing of the *E. coli* increased by about 40 times in blood samples taken immediately after the first infusion. The enhanced antibacterial activity persisted throughout the infusion period. When rh GM-CSF was administered SC, the neutrophils in the peripheral blood were stimulated for enhanced antibacterial capacity to the same degree as during the IV infusions. The antibacterial activity of the neutrophils from the control monkeys also increased slightly, possibly because of the low amounts of endotoxin added to the infusion fluid.

DISCUSSION

The results of the present study indicate that purified rh GM-CSF is both an effective stimulator of leukocytosis and an activator of the phagocytic function of mature neutrophils in vivo. The repeated administration of rh GM-CSF to rhesus monkeys over a seven-day period produced a steady rise in peripheral WBCs with peak response occurring on the last day of the dosing. The rise in peripheral WBC was mainly a result of increased levels of circulating neutrophils, which contributed to about 70% to 80% of the leukocytosis. In addition, an increase in the numbers of eosinophils and monocytes that contributed 12% to 15% and 2% to 7% respectively for the increased WBC counts were observed.

The prompt rise in peripheral blood neutrophil levels in response to the infused rh GM-CSF suggests that besides its established role as a stimulator of hematopoiesis, GM-CSF acts also as a releasing factor for granulocytes from the marrow reserve pool. Stimulation of hematopoiesis by rh GM-CSF either at the stem cell or at the myeloblast level would not contribute to the increased numbers of circulating neutrophils until at least five days after the start of the treatment.¹⁴⁻¹⁶ The release of marrow granulocytes into the circulation would obviously be limited by the granulocytes

available in the marrow. The marrow granulocyte reserve pool was estimated to be three to seven times the size of the total blood granulocyte pool in humans. Estimates made to the contribution of the marrow reserve pool to increased circulating granulocyte counts suggest that when the circulating granulocytes double, the marrow reserve pool would last between 37 and 72 hours depending on its size. With a circulating granulocyte number four times normal, the marrow reserve would exhaust in 13 to 24 hours.¹⁷ If rh GM-CSF treatments would just increase the marrow-release rate of granulocytes in monkeys without changing the production, one would predict a decrease in the marrow granulocyte reserve and an exhaustion of the system. This exhaustion should also be followed by a decline in peripheral blood granulocyte counts beginning two to four days after starting treatments. But in contrast in the present study, granulocyte levels increased steadily up to the last day of the seven-day treatment period and remained elevated by treating a monkey as long as 21 days.¹² The important question of whether or not the rh GM-CSF acts only as a releasing factor or as a stimulator of hematopoiesis was also addressed by comparing bone marrow aspirates before and after rh GM-CSF administration. An exhaustion of the granulocyte reserve pool by stimulating the release of these cells into the circulation would have depleted granulocytes from the bone marrow. Yet bone marrow aspirates taken either during or after the treatment with rh GM-CSF showed no granulocyte depletion of the marrow. The observation that also no changes in the cellular compositions of the marrow were found suggests that the sequential flow of cells through granulopoiesis was not disturbed. From these studies it can be concluded that GM-CSF plays an important role in the physiologic regulation of marrow granulocyte release as well as on its production.

One of the characteristics of the granulocyte system is the promptness with which it responds, eg, to infections.¹⁸ The response of this system to rh GM-CSF treatment in monkeys resembles that of an infectious stimulus. Therefore one can speculate that the response of the granulocyte system to an infection is mediated by the release of GM-CSF.

Feedback inhibition of granulopoiesis has long been thought to be essential to the balance that exists between production and utilization.¹⁹ Granulopoiesis simulated by a computer program demonstrated oscillations in production rates.²⁰ This view is supported by the cyclic production of neutrophils in congenital cyclic neutropenia and the appearance of cyclic neutropenia in myelosuppressed dogs.²¹ Mature neutrophils have been shown to inhibit colony formation in vitro²² and to suppress growth of granulocytes in marrow in implanted intraperitoneal diffusion chambers.²³ Substances derived from granulocytes have been reported to inhibit in vitro granulopoiesis.²⁴ The physiologic role of these inhibitors is at present speculative, but it could mean that high numbers of circulating granulocytes can suppress granulopoiesis in vivo. Although granulocyte counts were elevated up to five to six times normal in response to rh GM-CSF treatments, no feedback mechanism suppressing steady-state granulopoiesis and reducing granulocyte counts below normal values were observed after termination of rh GM-CSF treatments in monkeys.

The rise of peripheral blood neutrophil, monocyte, and eosinophil counts in response to the in vivo treatment with rh GM-CSF in monkeys reflects the in vitro observation that this factor also stimulates the proliferation of the corresponding progenitor cells in bone-marrow cell cultures. Although in vitro no lymphocyte colony formation was found in nonhuman-primate bone marrow cultures,¹² in vivo a two-fold to fivefold increase in lymphocyte numbers was observed. This lymphocytosis may represent an indirect effect of rh GM-CSF treatments on hematopoietic regulatory mechanisms. In vitro it was shown that in the presence of erythropoietin rh GM-CSF was capable of stimulating the proliferation of erythroid progenitors in bone marrow cells taken from a nonhuman primate species.¹² It was also suggested that GM-CSF acts directly on erythroid and multipotential progenitor cells, since highly enriched progenitors, depleted of T lymphocytes and monocytes, were also stimulated for colony formation.⁷ Increased reticulocyte counts were also found in control monkeys and can be interpreted as due to repeated blood sampling. Therefore it can be concluded that rh GM-CSF does not have an influence on the erythroid lineage in vivo.

It was particularly interesting that SC treatments (three times daily) were more effective in eliciting higher levels of neutrophils than IV infusions over a six-hour period. Thus the degree of the rh GM-CSF-induced neutrophilia was twofold higher than that obtained after IV infusions. Rh GM-CSF was shown to be cleared from the circulation with a half-life of approximately seven minutes.¹² Also another lymphokine, namely interleukin 2 (IL 2), was cleared from the blood stream rapidly ($t_{1/2}$ five to seven minutes).²⁵ If, however, IL 2 was administered SC in three doses equally throughout the day, IL 2 levels were maintained in the plasma over the entire 24-hour interval. This treatment schedule also showed increased therapeutic activity compared to once-a-day administration.²⁶ It was also found that slowly released IL 2 administered SC from a microosmotic pump was more effective in augmenting therapeutic efficacy than a single injection of the same total dose.²⁷ Therefore the

major factor determining the duration of the biological activity of IL 2 seems to be related to the release of this protein from the site of administration, an observation that may also be due to GM-CSF.

Besides their proliferative effects on committed granulocyte and monocyte progenitor cells, CSFs are also potent stimulators of the functional activity of mature cells. It is, therefore, logical to expect that IV-injected rh GM-CSF would influence the phagocytic activity of mature neutrophils in the circulation. The results of the present study indicate that activation of the peripheral blood neutrophils for increased generation of O_2^- occurred rapidly following the first dose of the CSF (within six hours) and persisted throughout the seven-day dosing regimens. In addition to the enhanced oxidative metabolism, the leukocytes effectively killed a smooth strain of *E coli*.

The dual role of CSF, namely that of the maturation of progenitor cells and the activation of mature cells in the body, has certain attractions. It suggests that the rapid changes in blood CSF levels after certain manipulations, eg, the injection of bacterial endotoxin,²⁸ are primarily to activate mature cells rather than for the stimulation of granulopoiesis.

It was particularly interesting that both the glycosylated mammalian cell-derived and the nonglycosylated *E coli*-derived rh GM-CSF induced a neutrophilia of the same magnitude and duration. The in vivo biological activity of glycosylated and nonglycosylated interferon α was also reported to be the same. Although the interferon carbohydrate side chains were altered by glycosidases, the clearance from the circulation was not changed.²⁹ Also glycosylated and nonglycosylated preparations of IL 2 showed similar biological activities in vivo.³⁰ In contrast, the nonglycosylated form of erythropoietin exerted only weak activity in vivo when compared with the glycosylated form.³¹ It is possible that small glycoproteins like interferon α , IL 2, and GM-CSF having molecular weights around 20 kd are mainly degraded by the kidney,³² whereas larger glycoproteins, eg, erythropoietin with a mol wt of 46 kd, are cleared by the hepatic pathway.³³ This different way of elimination of small and larger glycoproteins may be the reason for variations in the in vivo activity of the glycosylated and nonglycosylated form of some proteins.

The demonstration that rh GM-CSF induces leukocytosis in monkeys suggests a number of potential uses for this lymphokine in humans. For example, GM-CSF could be useful in restoring hematopoiesis in bone marrow transplantation (BMT) patients or in patients experiencing iatrogenic myelosuppression. Because the main function of granulocytes is to protect the body from foreign microorganisms, beneficial therapeutic effects of rh GM-CSF treatment can also be expected against infectious diseases.

S-100 Beta Positive Human T Lymphocytes: Their Characteristics and Behavior Under Normal and Pathologic Conditions

By Kiyoshi Takahashi, Tadashi Yoshino, Kazuhiko Hayashi, Hiroshi Sonobe, and Yuji Ohtsuki

The characteristics of human S-100 beta-positive T lymphocytes (S-100 beta⁺ T cells) and their fluctuation in peripheral blood under normal and various pathologic conditions were investigated. S-100 beta⁺ T cells were small lymphocytes with no particular subcellular structures and showed a proliferative response to mitogens. They were present mainly in peripheral blood under normal conditions but accumulated in T zones of lymph nodes with nonspe-

cific T-zone hyperplasia, where numerous interdigitating reticulum cells existed. In healthy adults approximately 1% to 4% (mean 3.4%) of peripheral blood mononuclear cells were S-100 beta⁺ T cells. The proportion of S-100 beta⁺ T cells in peripheral blood tended to significantly decrease (<0.5%) in patients with neoplastic diseases; this tendency was apparently related to tumor progression.

S-100 PROTEINS belong to a family of acidic calcium-binding proteins, such as calmodulin and myosin light chain, whose roles are unknown.^{1,2} Structurally, they are dimers of the alpha and beta subunits, and three distinctive forms, alpha-alpha(S-100a₀), alpha-beta(S-100a), and beta-beta(S-100b) exist.¹⁻⁴ Until recently S-100 proteins were considered to be specific for the nervous system, but recent immunohistochemical studies have revealed that they are widely distributed among human tissues, including lymphoid organs.⁵⁻¹¹ In the human lymphoid organs S-100 beta immunoreactivity is detected in T-zone histiocytes, namely interdigitating reticulum cells (IDC) and Langerhans cells.¹¹ S-100 immunoreactivity has also been detected in some human peripheral blood T cells bearing T-8 antigen.¹² The S-100 positive human T cells show solely S-100 beta subunit immunoreactivity, as demonstrated in the present study. Although the S-100 beta⁺ T cells are present in significant numbers in human peripheral blood, their properties and roles remain unknown. In the present study we attempted to characterize the S-100 beta⁺ T cells with respect to fine structure, mitogen response, membrane properties, and distribution in lymphoid tissues. In addition, to elucidate the role of S-100 beta⁺ T cells, we analyzed and compared their proportions in peripheral blood from healthy controls, from patients with advanced stages of neoplastic diseases, from patients with various stages of gastric cancer, and from patients with nonneoplastic diseases. The results were evaluated in relationship to ages, types, and stages of the diseases.

MATERIALS AND METHODS

Analysis on the Characteristics of Circulating S-100 Beta⁺ T Cells

Preparation of Cells

Peripheral blood mononuclear cells (PBM) were obtained from heparinized peripheral venous blood of healthy adults by Ficoll

Hypaque (FH) density gradient centrifugation, as described previously.¹² T cells were enriched by E rosetting method as described previously.¹² Non-E rosetted-cells were used as a B cell-enriched fraction. T gamma cells (IgG-Fc receptor-positive T cells) were isolated by rosetting technique using IgG-conjugated bovine erythrocytes. Briefly, 1×10^7 cells of T cell fraction were incubated with 5×10^8 bovine erythrocytes conjugated with rabbit IgG (IBL, Takasaki, Japan) for 30 minutes at 37°C. The rosetted cells were separated from nonrosetted cells by FH centrifugation. The erythrocytes in the rosette positive pellet were lysed with 0.85% Tris-NH₄Cl. Complement C3 receptor-positive cells (C3-R⁺ cells) were isolated from PBM by rosetting technique with the use of C3b-conjugated bovine erythrocytes (IBL, Takasaki, Japan) in the same manner. Enriched T cells, enriched B cells, T gamma cells (IgG-Fc-R⁺ T cells), IgG-Fc-R⁻ T cells, C3-R⁺ cells, and C3-R⁻ cells were examined.

Mitogen Stimulation

PBM were cultured in 10% fetal calf serum-supplemented RPMI 1640 containing 10 µg/mL of concanavalin A (con A, Pharmacia, Uppsala, Sweden) or 20 µg/mL of phytohemagglutinin (PHA-M, Gibco, NY) for three days in a CO₂ incubator. The stimulated cells were examined immunocytochemically. The percentage of S-100 beta⁺ cells was compared with that of nontreated PBM cultured for three days without mitogen.

Preparation of Antibodies

Affinity purified rabbit antibodies specific for S-100 alpha or beta subunit were used. The preparation and specificities of these antibodies were described previously.^{10,11} For T cell staining we used monoclonal antibodies (MoAbs), Leu-1 (Becton Dickinson Monoclonal Center Inc, Mountain View, CA), and MT-1 (Bioscience, Switzerland), which recognize all T cells and monocytes but not B cells. To eliminate monocytes that were also positive for MT-1, we used rabbit antilysozyme antisera (DAKO, Denmark), which could specifically detect monocytes. We used MT-1 so that MT-1 could clearly recognize T cells even after formaldehyde fixation, which was essential for detection of the water-soluble S-100 beta subunit. For S-100 and lysozyme staining, we used peroxidase antiperoxidase (PAP) method using goat antirabbit IgG (DAKO, Denmark) and peroxidase antiperoxidase complex (DAKO, Denmark). For Leu-1 and MT-1 staining we used a Vectastain ABC kit (Vector Laboratory Inc, Burlingame, CA).

Immunoperoxidase Staining at the Light Microscopic Level

Cells were fixed in 2% paraformaldehyde solution for five minutes at room temperature, washed with phosphate-buffered saline (PBS), and air dried on glass slides. The cells were immersed in -20°C acetone for ten minutes and incubated in methanol containing 0.3%

H₂O₂ for 15 minutes to block endogenous peroxidase activity. After washing with PBS the cells were incubated successively with 10% normal goat serum and rabbit antibodies against either S-100 alpha or S-100 beta subunit (15 µg/mL) for 60 minutes. After washing with PBS the cells were stained by PAP method, as described previously.¹² For Leu-1 or MT-1 staining, cells treated with normal goat serum were incubated with MoAb Leu-1 (1:20) or MT-1 (1:10) and stained by the ABC method according to the staining procedure of a Vectastain ABC kit.

Immunoperoxidase Staining at the Electron Microscopic Level

Affinity-purified antibody to S-100 beta subunit was conjugated with horseradish peroxidase (HRPO) by the method of Nakane and Kawaoi.¹³ Enriched T cells were fixed, stained with the HRPO-conjugated anti-S-100 beta, embedded in Epon 812, and examined as described previously.¹²

Analysis of Morphology and Distribution of S-100 Beta⁺ T Cells in Human Lymphoid Tissues

Preparation of Lymphoid Tissues

Each of the five formalin-fixed specimens of normal lymph nodes, thymus, and spleen was obtained at autopsy. Fifteen lymph nodes with nonspecific lymphadenitis showing marked T-zone hyperplasia were obtained by surgical biopsy. Tissues were routinely fixed in formalin and embedded in paraffin.

Immunoperoxidase Staining of Tissues at Light Microscopic Level

Deparaffinized sections were stained with rabbit anti-S-100 beta antibody by PAP method as described previously.¹⁰

Immunoelectron Microscopic Analysis

Slices 60-µm thick were cut from formalin-fixed specimens by an Oxford Vibratome. The slices were stained with anti-S-100 beta by indirect immunoperoxidase method using HRPO-conjugated goat antirabbit IgG (DAKO, Denmark), as described in our previous paper.⁸

Analysis of the Fluctuation of Circulating S-100 Beta⁺ T Cells Under Normal and Pathologic Conditions

Selection of Patients and Controls

Controls. Healthy adult donors consisted of 38 individuals 20 to 92 years of age, 24 males and 14 females. Of 38 healthy individuals, 24 persons were under 60 years of age (mean = 30 years, younger age group) and 14 persons were over 60 years of age (mean = 76 years, older age group).

Patients with advanced neoplastic diseases. Patients of this group had a dissemination or systemic metastasis of the neoplasm. They consisted of 49 individuals 22 to 88 years of age, 25 males and 24 females, including 15 patients with lung cancer (six adenocarcinomas, five squamous cell carcinomas, four small cell carcinomas), 13 patients with gastric carcinoma, seven patients with non-Hodgkin malignant lymphoma, three patients each with gallbladder carcinoma and mammary carcinoma, two cases with hepatocellular carcinoma, and single cases with carcinomas of the thyroid, pancreas, rectum, renal clear cells, esophagus, and larynx.

Patients with early-stage gastric cancer. Patients of this group had a gastric adenocarcinoma restricted to gastric mucosa and showed neither clinical symptoms nor abnormalities in laboratory

tests. The patients consisted of seven individuals 46 to 70 years of age, three males and four females.

Patients with a postoperative status of gastric cancer. Patients in this group had received surgical therapy over 2 years before lymphocyte analysis and had a curative status without evidence of metastasis or recurrence. The patients consisted of 16 individuals 30 to 80 years of age, nine males and seven females.

Patients with non-neoplastic diseases. Patients consisted of 39 individuals 24 to 81 years of age, 25 males and 14 females, including eight patients with diabetes mellitus; four patients each with chronic active hepatitis, liver cirrhosis, and nephrotic syndrome; three patients each with lower respiratory disease and hypertension; two patients each with systemic lupus erythematosus (SLE) and chronic thyroiditis; and individual patients with chronic pancreatitis, gastroenteritis, polymyositis, progressive systemic sclerosis (PSS), sialoadenitis, splenic infarction, primary myocardopathy, necrotizing lymphadenitis, and cerebrovascular disease. None of the patients received chemotherapy or radiotherapy during the month before lymphocyte analysis. The patients with SLE, nephrotic syndrome, polymyositis, and PSS received extensive steroid therapy.

Analysis of the Percentages of Circulating S-100 Beta⁺ T Cells and Total T Cells

PBM were obtained from 5 mL of heparinized peripheral venous blood of the healthy controls and patients as described above. PBM of all persons were stained with anti-S-100 beta as described above. Besides S-100 beta staining, PBM from patients with gastric cancer, including 13 advanced cases, seven early cases, and 16 cases with postoperative stages, were stained with MT-1 and lysozyme to analyze the proportions of total T cells. Both S-100 beta-positive and negative cells were precisely counted by tracing these cells in pictures of nonselected fields until they reached 1,000 in number, and the percentage of the positive cells was calculated. After four counts the average percentage was used as the result. The percentages of total T cells were calculated by counting MT-1 positive cells after eliminating lysozyme-positive monocytes.

RESULTS

Characteristics of Circulating S-100 Beta⁺ T Cells

S-100 Subunit Immunoreactivities

S-100 beta⁺ cells were detected exclusively in the T cell-enriched fraction. Approximately 4% of T cells were positive for the S-100 beta subunit (Fig 1A). Almost all cells of this fraction were positive for Leu-1, but none was positive for S-100 alpha subunit. No S-100 beta⁺ cells were detected in the B cell-enriched fraction. Monocytes in the B-enriched fraction were clearly positive for S-100 alpha. These findings indicated that approximately 4% of the human peripheral T cells contained S-100b protein, a dimer of S-100 beta subunit. Therefore we named them S-100 beta⁺ T cells.

Response to Mitogens

The majority of PBM from healthy donors treated with con A or PHA-M for three days displayed a marked blastic change, and some of the blastic cells were clearly positive for S-100 beta. Occasionally S-100 beta immunostaining was found in mitotic cells (Fig 1B). The percentages of S-100 beta positive cells in con A- or PHA-treated PBM were 3.5 or 3.4 respectively and were almost equivalent to that in non-treated PBM (3.3%). These findings indicated that S-100 beta⁺ T cells had an ability to display a proliferative response

Fig 1. (A) S-100 beta immunoperoxidase staining of T cell-enriched fraction of healthy donors. Approximately 4.0% of T cells of peripheral blood are S-100 beta⁺ T cells (original magnification $\times 80$; current magnification $\times 60$). (B) S-100 beta-immunoperoxidase staining of peripheral blood mononuclear cells stimulated by con A for three days. Note a mitotic cell showing intense S-100 beta immunoreactivity (arrow) (original magnification $\times 1,000$; current magnification $\times 750$). (C, D) Immunoelectron micrographs of S-100 beta⁺ T cells in peripheral blood of healthy donor. S-100 beta⁺ T cells possess narrow cytoplasm with scanty cellular organelles and round (A) or singly indented (B) nuclei (original magnification $\times 9,300$; current magnification $\times 6,975$).

to con A and PHA, and the S-100b protein in the cytoplasm was stable during the proliferative reactions.

IgG-Fc Receptor

S-100 beta immunoreactivity was detected in approximately 5% of T gamma cells. S-100 beta immunoreactivity was also detected in about 3% of IgG-Fc-R⁻ cells. Of 1×10^7 T cells, approximately 20% were IgG-Fc-R positive (T gamma cells), and 80% were IgG-Fc-R negative. From these findings it was estimated that about 30% of S-100 beta⁺ T cells expressed IgG-Fc receptor, but the rest did not.

Complement C3 Receptor

No S-100 beta⁺ T cells were detected in C3-R⁺ fraction. S-100 beta⁺ T cells were found exclusively in C3-R⁻ fraction. These findings indicated that S-100 beta⁺ T cells did not express complement C3 receptor.

Fine Structure of Circulating S-100 Beta⁺ T Cells

Ultrastructurally S-100 beta⁺ T cells in peripheral blood were small, smooth-surfaced lymphocytes containing round or singly indented nuclei and had narrow cytoplasm with scanty cellular organelles (Figs 1C, 1D). Immunoreaction products were evenly distributed throughout the cytoplasm except for mitochondria and vacuoles. Usually nuclei were devoid of the reaction products.

Morphology and Distribution of S-100 Beta⁺ T Cells in Human Lymphoid Tissues

Immunohistochemistry

In each case of normal lymph node, thymus, and spleen, only a small number of S-100 beta⁺ T cells were detected in T zones. Thus under normal conditions S-100 beta⁺ T cells circulated mainly in the peripheral blood. However, relatively large numbers of S-100 beta⁺ T cells were found in lymph nodes with reactive T-zone hyperplasia, and these cells were found exclusively in T zones where numerous S-100 beta⁺ IDC were present (Fig 2A). In addition, it was of great interest that a variety of S-100 beta⁺ cells showing morphological transition from lymphocytes to IDC were frequently observed in these areas (Fig 2B).

Immunoelectron Microscopy

S-100 beta immunoreactivity was detected in IDC and small lymphocytes (Figs 3A, 3C). As shown in our previous study,⁹ S-100 beta⁺ IDC possessed considerable cytoplasm with interdigitating projections and irregularly shaped nuclei with evenly distributed nuclear chromatin (Fig 3C). S-100 beta⁺ T cells in lymph nodes were small lymphocytes with singly indented nuclei and narrow cytoplasm without characteristic subcellular structure (Fig 3A). Occasionally small lymphocyte-sized or intermediate-sized cells that possessed

Fig 2. S-100 beta immunoperoxidase staining of a lymph node with reactive T-zone hyperplasia. (A) Note numerous S-100 beta⁺ T cells in T zone where large numbers of S-100 beta-positive interdigitating reticulum cells are present (original magnification $\times 100$; current magnification $\times 70$). (B) A number of S-100 beta-positive cells showing morphological transition from lymphocytes to S-100 beta-positive interdigitating reticulum cells (original magnification $\times 400$; current magnification $\times 280$).

round or irregular nuclei and interdigitating cytoplasmic projections were found to be positive for S-100 beta subunit (Fig 3B).

The Fluctuation of S-100 Beta⁺ T Cells Under Normal or Pathologic Conditions

Healthy Controls

The percentages of circulating S-100 beta⁺ T cells in the peripheral blood of 38 healthy controls ranged from 0.5 to 10.0, and the mean was 3.4% (Fig 4). No sexual difference was detected. As for ages, the mean of the older age group (over 60 years of age) was 2.9%, and that of the younger age group (under 60 years of age) was 3.6%. The former was statistically lower than the latter (*t* test, $P < 0.05$). Of 38 healthy controls, only four persons showed less than 1.0%, but none of them showed less than 0.5%. Thus we concluded

that a percentage lower than 0.5 indicated an abnormally low proportion of S-100 beta⁺ T cells in peripheral blood.

Patients With Advanced Stages of Neoplastic Diseases

In almost half of the patients (24 of 49), the ranges for S-100 beta⁺ T cells were less than 0.5% (Fig 4). Of these 24 patients, 18 subjects showed less than 0.2%. About two thirds of subjects showed less than 1.0%. The mean was 0.9%, and the lowest percentage was 0.035, which was observed in a patient with gastric cancer. A marked decrease in S-100 beta⁺ T cells was observed in both young and old individuals with advanced cancer but was not correlated with the ages as shown in Fig 4. As for types of the diseases, a percentage of S-100 beta⁺ T cells lower than 0.5 was observed in eight of 13 patients with gastric cancer, in seven of 15 patients with lung cancer (four of six cases with adenocarcinoma, two of four

Fig 3. Immunoelectron micrographs of S-100 beta-positive cells in a lymph node with reactive T-zone hyperplasia. (A) A small lymphocyte showing S-100 beta immunoreactivity. The lymphocyte contains a singly indented nucleus and narrow cytoplasm with scanty cellular organelles (original magnification $\times 6,000$; current magnification $\times 4,500$). (B) S-100 beta-positive cells of lymphocyte-size with irregular nucleus and interdigitating cytoplasmic processes (original magnification $\times 5,000$; current magnification $\times 3,750$). (C) Interdigitating reticulum cells showing S-100 beta immunoreactivity. The cell contains an irregular nucleus with evenly distributed nuclear chromatin and possesses wide cytoplasm showing abundant cellular organelles and dendritic cytoplasmic projections (original magnification $\times 3,300$; current magnification $\times 2,475$).

Fig 4. The percentage of S-100 beta⁺ T cells in peripheral blood from healthy controls (A), patients with advanced neoplastic diseases (B), and patients with non-neoplastic diseases (C). ●, individual under 60 years of age; ○, individual over 60 years of age.

patients with squamous cell carcinoma, and one of four patients with small cell carcinoma), in three of seven patients with non-Hodgkin lymphoma, in two of three patients with mammary carcinoma, in one of two patients with hepatocellular carcinoma, and in one of three patients with gallbladder carcinoma, and in single patients each with esophageal carcinoma and laryngeal carcinoma.

Patients With Early or Postoperative Status of Gastric Cancer

In contrast to the patients with advanced gastric cancer, only one of seven patients with early gastric cancer and none of 16 patients with postoperative status of gastric cancer ranged less than 0.5%. No statistical difference in the percentage of S-100 beta⁺ T cells was noticed between these groups and healthy controls (Fig 5).

Patients With Non-neoplastic Diseases

Of 39 individuals, seven persons showed less than 0.5%, including two of eight patients with diabetes mellitus, two of four patients with chronic active hepatitis, two of two patients with SLE, and one of three patients with hyperten-

Fig 5. The percentage of S-100 beta⁺ T cells in peripheral blood of patients with early stage gastric cancer (A), patients with advanced stages of gastric cancer (B), and patients with a curative status of postoperative gastric cancer (C).

sion. In contrast to patients with advanced neoplastic diseases, the majority of this group (29 out of 39) showed more than 1.0% (mean = 2.3%). The highest percentage was 19.0, observed in patients with nephrotic syndrome (Fig 5A).

The Proportions of Total T Cells in Patients With Gastric Cancer

The percentages of total T cells recognized by MT-1 in peripheral blood of these groups ranged from 60 to 85, and no statistical difference was detected among these three groups.

DISCUSSION

Previously we reported that the S-100 positive T lymphocytes expressed T-3, T-8, and T-11 antigens but not T-4, HLA-DR, Leu-7, or OKM1 antigens.¹² In the present study we further characterized the S-100 positive human T lymphocytes. They showed solely S-100 beta subunit immunoreactivity and ultrastructurally were small lymphocytes with no characteristic subcellular structure; they displayed a proliferative response to con A and PHA. These findings further indicated the distinct T cell nature of S-100 beta⁺ T cells. The S-100 beta⁺ T cells were present mainly in peripheral blood under normal conditions. Approximately 3% to 4% of peripheral blood mononuclear cells were S-100 beta⁺ T cells in healthy persons. We also found that the proportion of circulating S-100 beta⁺ T cells of healthy persons displayed a tendency to decrease with age. In contrast, a markedly decreased percentage of S-100 beta⁺ T cells (less than 0.5%) was observed in nearly 50% of patients

with advanced neoplastic diseases. The marked decrease in the percentage of S-100 beta⁺ T cells was not significantly related to age or histologic types of tumors. The present analysis of the patients with various stages of gastric cancer also revealed that such a decrease was apparently related to the advanced stage of the disease. As for T cell profiles, no significant difference in total T cell proportion was observed among the patients with various stages of gastric cancer. Although S-100 beta⁺ T cells have been shown to belong to the T-8⁺ cell subpopulation,¹² there has, as far as we know, been no report that indicates the proportional decrease of T-8⁺ cells in cancer patients accompanied by tumor progression, which could account for such a marked proportional decrease of S-100 beta⁺ T cells. Ginn et al¹⁴ reported that in the patients with primary lung cancer, no significant difference in the proportion of total T cells (T-3⁺), helper/inducer T cells (T-4⁺), or suppressor/cytotoxic T cells (T-8⁺) was detected as compared with healthy controls, although their absolute numbers differed according to the histologic types of the tumors. It has been shown that the proportion of T gamma cells may increase in the patients with advanced cancer.^{15,16} We found, however, that the vast majority of T gamma cells was negative for S-100 beta. Thus it was likely that the proportional fluctuation of S-100 beta⁺ T cells was independent of those of other types of T cells. Proportional independence of S-100 beta⁺ T cells from other T cell subsets suggests that their roles are distinct from those of other T cell subsets. It is also possible that such a marked proportional decrease of S-100 beta⁺ T cells resulted in or from certain immunologic abnormalities in patients with advanced neoplasms. It has been well documented that cancer patients may display various immunodeficiency disorders correlating with stages of disease,¹⁷⁻²¹ which have generally been considered to be important for tumor cells in escaping from the host's immunologic surveillance system. Therefore it is possible that a marked proportional decrease in S-100 beta⁺ T cells may be linked to known or unknown immunodeficiency disorders in the patients with advanced cancer.

In this study we found that S-100 beta⁺ T cells circulated mainly in peripheral blood under normal conditions, but in certain pathologic conditions they accumulated in T zones of lymphoid tissue where numerous IDC were usually present. Moreover a considerable number of S-100 beta-positive cells of various intermediate sizes between lymphocytes and IDC were detected in these areas. They seemed to be in the course of conversion from lymphocytes into IDC. Such coexistence of S-100 positive, small, lymphocyte-like cells and intermediate cells with IDC in T zones was also noticed and reported by Watanabe et al.²² They regarded the S-100 positive, small, lymphocyte-like cells and intermediate cells as precursors of IDC but did not recognize S-100 positive, small, lymphocyte-like cells as T lymphocytes. However, the present immunoelectron microscopic findings clearly indicated that they possessed the distinct morphological features of small lymphocytes. We also detected IL2 receptor on con A-stimulated S-100 beta⁺ T cells (unpublished finding). As shown in our previous¹² and present studies, the S-100 positive, lymphocyte-like cells definitely are T cells, and they form a novel human T cell subset, namely, the S-100 beta-positive T cell subset. Thus the question as to whether S-100 beta⁺ T cells are precursors of IDC and their related cells should be settled because the origin of IDC still remains undetermined. There are, however, extensive differences between S-100 beta⁺ T cells and IDC. Namely, IDC and its related cells have been shown to possess HLA-DR, T-6 antigens, complement receptor, ATPase activity, none of which has been proved in S-100 beta⁺ T cells.^{12,23} IDC have generally been considered and accepted to be antigen-presenting cells for T cells but not to be cells originating from T lymphocytes.²⁴ At present we have no evidence to support the view that S-100 beta⁺ T cells can convert into IDC, except for the immunomorphological findings. Further studies should be made to resolve these questions.

Recently Ruco et al²⁵ reported an unusual case of lymph node neoplasm in which tumor cells were positive for S-100 protein and expressed sheep erythrocyte receptor, T-3, T-8, and T-11 antigens. According to their observations, the neoplastic cells with S-100 immunoreactivity undoubtedly were T cells. Thus their particular case of lymph node neoplasm implies the presence in a neoplastic disorder of S-100 beta⁺ T cells. In fact, we found a patient with a neoplastic proliferation of S-100 beta⁺ T cells in peripheral blood (unpublished data). Therefore we are considering proposing a new entity of T cell malignancy, namely S-100 beta⁺ T cell leukemia/lymphoma.

Recently, Nomori et al²⁶ suggested the important role of S-100 positive T-zone histiocytes, IDC, and Langerhans cells in antitumor immunity of humans. They found that the degree of the density of S-100 positive T-zone histiocytes, but not that of ordinary macrophages, in the primary site of nasopharyngeal carcinoma had a significant relationship to prognosis. Together with our findings it is more likely that S-100 beta-positive cells in the human immune system may play important roles in antitumor immunity.

ACKNOWLEDGMENT

We thank Drs H. Tokuoka, and T. Miura, Kochi Prefectural Central Hospital, for giving us the materials of and information on the patients examined in this study and Conrad Zagoly, Jr, PhD, Kochi Medical School, for his critical review of the manuscript.

Fibrinogen-Independent Aggregation and Deaggregation of Human Platelets: Studies in Two Afibrinogenemic Patients

By M. Cattaneo, R.L. Kinlough-Rathbone, A. Lecchi, C. Bevilacqua, M.A. Packham, and J.F. Mustard

Platelets from two afibrinogenemic patients were used to determine whether fibrinogen is essential for platelet aggregation and to examine whether released fibrinogen contributes to the stabilization of platelet aggregates when platelets have been induced to aggregate and release their granule contents by stimulation with thrombin. The addition of adenosine diphosphate (ADP) to platelet-rich plasma (PRP) or to suspensions of washed platelets from the afibrinogenemic patients caused the formation of small aggregates, which was either not inhibited or only slightly inhibited by the F(ab')₂ fragments of an antibody to fibrinogen but was inhibited by an antibody (10E5) to glycoprotein IIb/IIIa. Thus there is a component of ADP-induced platelet aggregation that is not dependent on fibrinogen or other plasma proteins but is dependent on glycoprotein IIb/IIIa.

FIBRINOGEN is believed to be important in human platelet aggregation because platelets from patients with afibrinogenemia aggregate poorly in response to adenosine diphosphate (ADP),¹⁻⁴ and washed human platelets also aggregate poorly in response to ADP if they are suspended in a medium without added fibrinogen.⁵⁻¹² In addition, thrombasthenic platelets that lack the fibrinogen receptor glycoprotein IIb/IIIa do not aggregate in response to any agonist,¹³⁻²⁰ and antibodies directed against glycoprotein IIb/IIIa inhibit platelet aggregation and the binding of fibrinogen.²¹⁻²⁵ However, despite these observations it is not known whether fibrinogen is essential for platelet aggregation. Several observations indicate that a small extent of ADP-induced aggregation occurs without the addition of fibrinogen to suspensions of washed human platelets in a medium containing 2 mmol/L Ca²⁺ and 1 mmol/L Mg²⁺, in which ADP does not cause appreciable release of platelet granule contents,^{1,12,26} and in which suspensions of washed platelets from rabbits aggregate extensively in response to ADP without the addition of fibrinogen to their suspending medium.^{27,28}

When aggregation is induced by agents that cause the release of granule contents, released fibrinogen is thought to be responsible for aggregation. Tollefsen and Majerus²⁹ reported that Fab fragments of an antibody to fibrinogen inhibited thrombin-induced aggregation. However, although Legrand et al.³⁰ also found that Fab fragments of an antibody to fibrinogen were able to partially inhibit platelet aggregation caused by very low concentrations of thrombin, high concentrations were not inhibited. Further evidence that aggregation can occur without fibrinogen includes the observations of Turitto et al.,³¹ who have shown that platelets from the native blood of an afibrinogenemic patient form large aggregates in a Baumgartner flow chamber, and the studies of Soria et al.,¹ showing that washed platelets from afibrinogenemic subjects aggregate normally in response to thrombin.

It has not been established whether fibrinogen plays a major role in preventing platelet deaggregation. When platelets aggregate without releasing granule contents, deaggregation occurs readily, and the fibrinogen that has been bound

There was little difference in the extent of aggregation and the release of granule contents of normal and afibrinogenemic platelets in response to the release-inducing agents collagen, platelet-activating factor (PAF), sodium arachidonate, or thrombin. With normal or afibrinogenemic platelets, aggregation by thrombin (0.2 U/mL or higher) was not inhibited by the F(ab')₂ fragments of an antibody to human fibrinogen. Deaggregation by combinations of inhibitors of platelets aggregated by 1 U/mL thrombin showed no difference between platelets from afibrinogenemic and control subjects, indicating that released fibrinogen does not make a major contribution to the stabilization of platelet aggregates formed by thrombin stimulation.

during aggregation readily dissociates.^{12,32,33} In contrast, when the release of granule contents takes place, platelets do not deaggregate readily, and even when they are induced to deaggregate, only some of the bound fibrinogen dissociates.³⁴

Platelets from afibrinogenemic patients provided an opportunity to determine whether fibrinogen is essential for platelet aggregation and to examine the contribution of released fibrinogen to the stabilization of thrombin-induced platelet aggregates.

MATERIALS AND METHODS

Materials. ¹⁴C-serotonin (¹⁴C-5-hydroxytryptamine-3'-creatinine sulfate, 50 mCi/mmol) was from Amersham Corporation, Arlington Heights, IL. Bovine serum albumin, Pentex fraction V, was from Miles Laboratories, Elkhart, IN. Apyrase was prepared from potatoes by the method of Molnar and Lorand.³⁵ The activity of this preparation in the final platelet-suspending medium was such that the enzyme (1 μL/mL) converted 0.25 μmol/L adenosine triphosphate (ATP) to adenosine monophosphate (AMP) within 120 seconds at 37°C. Human fibrinogen (grade L, AB Kabi, Stockholm, Sweden) was pretreated with diisopropylfluorophosphate (DFP, Sigma Chemical Co, St. Louis)³⁶ and was partially purified by the method of Lawrie et al.³⁷ Chymotrypsin, ADP, collagen, and sodium arachidonate were from Sigma. Heparin was from Pentapharma (Basel, Switzerland). Synthetic platelet-activating factor (PAF,

1-O-octadecyl-2-acetyl-sn-glycerol-3-phosphoryl-choline) was from Bachem Feinchemikalien (Bubendorf, Switzerland). Thrombin was from Miles and PGE₁ from the Upjohn Company (Kalamazoo, MI). A monoclonal antibody (MoAb) to GPIIb/IIIa (10E5) was kindly provided by Dr Barry Coller (Stony Brook, NY) and was dialyzed against 0.14 mol/L NaCl solution before use. F(ab')₂ fragments of an antibody to human fibrinogen raised in goats were from Cappel (Malvern, PA); F(ab')₂ fragments of nonimmune IgG were from the same source. Sodium arachidonate and PGE₁ were prepared as previously described.^{38,39} Acid-soluble collagen was prepared by the method of Cazenave et al.⁴⁰ All other solutions were dissolved in modified Tyrode's solution. Citrated platelet-rich plasma (PRP) and suspensions of washed human platelets were prepared as described previously.^{11,41}

Aggregation and release. Platelet aggregation and the release of ¹⁴C-serotonin from prelabeled platelets was measured as described previously.^{41,42} Release of ATP from platelets was measured in a lumi-aggregometer (Chronolog, Haverton, PA).

Platelet count. The platelet count in PRP was adjusted to 350,000/ μ L; in suspensions of washed platelets it was 500,000/ μ L.

Fibrinogen assay. Platelet and plasma fibrinogen were measured using a fibrinopeptide A assay (FPA) kit (Mallinckrodt, St. Louis). FPA was freed from the fibrinogen by incubation with thrombin (4 U/mL) for two hours at 37°C. For measurement of platelet fibrinogen, platelets were treated with Triton X100, and the lysate was incubated with thrombin.

Characteristics of patients. Both patients with afibrinogenemia were young females (18 and 19 years of age) with a history of bleeding episodes dating from early childhood. Their bleeding times were prolonged (12 minutes and 18 minutes respectively, control 2.5 to seven minutes) and both the prothrombin times and partial thromboplastin times were greater than 600 seconds (controls 13 seconds and 28 seconds respectively). Neither patient had detectable amounts of plasma fibrinogen, as measured by the fibrin polymerization time (Bonomelli, Milan, Italy).

RESULTS

Fibrinogen concentrations. The concentrations of fibrinogen in the platelets of the afibrinogenemics and normal subjects are shown in Table 1. Both patients had plasma fibrinogen concentrations of approximately 3 μ g/mL.

Citrated PRP. The addition of ADP to citrated PRP prepared from the blood of the two afibrinogenemic patients caused the formation of small platelet aggregates; the addition of fibrinogen enhanced the response (Fig 1). Collagen, PAF, or sodium arachidonate induced more extensive aggregation of afibrinogenemic platelets, although the extent of aggregation was somewhat less than in PRP prepared from normal subjects (Fig 2). Aggregation of the afibrinogenemic platelets in response to arachidonate occurred after a lag phase, whereas normal platelets aggregated more rapidly. The amount of ATP released in response to the agonists was similar to or less than the amount released from normal platelets under the conditions used (Fig 2).

Table 1. Platelet Fibrinogen Concentrations in Patients With Afibrinogenemia and in Control Subjects

Subjects	n	Platelet Fibrinogen μ g/ 10^9 Platelets
Patient I	1	14.2
Patient II	3	8.6 $\pm$ 2.1
Controls	9	312.0 $\pm$ 17.0

Mean values $\pm$ SEM.

Fig 1. Platelet aggregation induced by ADP (2 μ mol/L) in citrated PRP obtained from the blood of two patients with afibrinogenemia. The upper tracings show the enhancement of aggregation induced by fibrinogen (FIB; 400 μ g/mL) added 30 seconds before the ADP. Platelet count: 350,000/ μ L.

To investigate the possible contribution to the extent of ADP-induced aggregation of the small amount of fibrinogen in afibrinogenemic plasma, the effect of F(ab')₂ fragments of an antibody to human fibrinogen was investigated. There was no inhibitory effect on aggregation induced by 2 μ mol/L ADP in comparison with control samples to which nonimmune F(ab')₂ fragments had been added; aggregation curves with the nonimmune fragments were superimposable on aggregation curves to which no F(ab')₂ fragments were added (Fig 3A). Addition of 8 μ g/mL of fibrinogen to afibrinogenemic PRP enhanced aggregation to some extent, and this enhancement was eliminated by the F(ab')₂ fragments of the antibody to fibrinogen (Fig 3B). Again, the aggregation curve obtained with nonimmune control F(ab')₂ fragments was superimposable on the aggregation curve obtained with only 8 μ g/mL fibrinogen added before the ADP.

Suspensions of washed platelets. For these experiments the platelets were resuspended in Tyrode-albumin solution, which is a balanced salt solution containing 2 mmol/L

Fig 2. Platelet aggregation induced by ADP (2 μ mol/L), collagen (2 μ g/mL), PAF (0.25 μ mol/L), or sodium arachidonate (1 mmol/L) in citrated PRP prepared from the blood of an afibrinogenemic patient (the lower tracing in each panel) and a normal control (the upper tracing). The amount of ATP released (μ mol/L) is indicated beside the aggregation tracings. Platelet count: 350,000/ μ L. Results shown are for patient II, but similar results were obtained with patient I.

Fig 3. Platelet aggregation induced by ADP (2 $\mu\text{mol/L}$) in citrated PRP obtained from patient II. (A) Comparison of the effect of F(ab')_2 fragments of an antibody to fibrinogen (F(ab')_2 AF; 220 $\mu\text{g/mL}$) with F(ab')_2 fragments of nonimmune IgG (F(ab')_2 NI; 250 $\mu\text{g/mL}$). The aggregation curve obtained without the addition of F(ab')_2 fragments was superimposable on the F(ab')_2 NI curve. Tyrode's solution (TYR) was added to maintain constant volumes. (B) Similar to (A) except fibrinogen (FIB) 8 $\mu\text{g/mL}$ or 400 $\mu\text{g/mL}$ was added before ADP. Again, the aggregation curve obtained without the addition of F(ab')_2 fragments was superimposable on the F(ab')_2 NI curve. Platelet count: 400,000/ μL .

calcium, 1 mmol/L magnesium, 0.35% albumin and apyrase. In this medium ADP in the presence of fibrinogen causes only the primary phase of aggregation of normal platelets, regardless of the concentration of ADP used^{26,41}; thromboxane formation does not occur, and there is little or no release of the contents of the platelet storage granules.⁴³

Figure 4 shows that ADP caused washed platelets from both an afibrinogenemic patient and from a normal subject to aggregate to a small extent. Microscopic examination confirmed that some of the platelets were present as small aggregates. The addition of fibrinogen before ADP enhanced the aggregation response and resulted in the formation of large aggregates (Fig 4). In all cases aggregation was followed by deaggregation.

With both the normal and afibrinogenemic platelets the small amount of aggregation that was observed in the absence of fibrinogen was either not inhibited or only slightly inhibited by the F(ab')_2 fragments of an antibody to fibrino-

Fig 4. Platelet aggregation induced by ADP (20 $\mu\text{mol/L}$) added to suspensions of washed platelets in a medium containing 2 mmol/L Ca^{2+} , 1 mmol/L Mg^{2+} , albumin (0.35%), and apyrase. The upper tracings show the enhancement of aggregation caused by fibrinogen (FIB; 400 $\mu\text{g/mL}$) added 30 seconds before the ADP (Patient II).

gen that completely inhibited the potentiation of aggregation caused by the addition of fibrinogen (3 to 11 $\mu\text{g/mL}$) (Fig 5). (Control experiments were done with nonimmune F(ab')_2 fragments.) However, an antibody to glycoprotein IIb/IIIa (10E5) at a final concentration of 10 $\mu\text{g/mL}$ completely inhibited platelet aggregation induced by 10 to 20 $\mu\text{mol/L}$ ADP but had no effect on the shape change of the platelets.

There was little difference in the extent of aggregation and the release of granule contents of normal and afibrinogenemic platelets in response to thrombin (0.2 to 1.0 U/mL; Fig 6). In these experiments the addition of hirudin two minutes after thrombin did not lead to deaggregation of the platelets from either the normal or afibrinogenemic patient (data not shown). Aggregation by thrombin at a concentration of 0.2 U/mL or higher was not inhibited by the F(ab')_2 fragments of an antibody to human fibrinogen (Fig 6).

Deaggregation. To investigate the possible role of fibrinogen in preventing deaggregation, we examined the effect of several combinations of inhibitors that we have previously shown cause the deaggregation of human platelets aggregated by thrombin.⁴⁴ Figure 7 shows the effect of the combination of hirudin, EDTA, and chymotrypsin two minutes after the addition of thrombin to suspensions of washed platelets. The rate and extent of deaggregation was practically identical for the normal and afibrinogenemic platelets. Inhibitors that did not deaggregate either type of platelet in the presence of hirudin were PGE_1 (10 $\mu\text{mol/L}$), chymotrypsin (10 U/mL), apyrase (40 $\mu\text{L/mL}$), EDTA (2.5 mmol/L), chymotrypsin plus PGE_1 , or chymotrypsin plus apyrase. No

Fig 5. Platelet aggregation induced by ADP (20 $\mu\text{mol/L}$) added to suspensions of washed platelets in a medium containing 2 mmol/L Ca^{2+} , 1 mmol/L Mg^{2+} , albumin (0.35%), and apyrase. Upper pairs of tracings: Normal platelets. Lower pairs of tracings: Afibrinogenemic platelets (Patient II). (a) Represents the response of platelets to ADP in the presence of added fibrinogen (FIB, 8 $\mu\text{g/mL}$). (b) Represents the response of platelets to ADP in the absence of added fibrinogen. Tyrode's solution (TYR) was added to control samples to maintain constant volumes. The additions were made at the points indicated by the arrows. The concentration of the F(ab')_2 fragments of nonimmune IgG (F(ab')_2 NI) was 150 $\mu\text{g/mL}$; the concentration of the F(ab')_2 fragments of an antibody to fibrinogen (F(ab')_2 AF) was 100 $\mu\text{g/mL}$.

Fig 6. Platelet aggregation induced by thrombin (0.2 U/mL) added to suspensions of washed platelets in a medium containing 2 mmol/L Ca^{2+} , 1 mmol/L Mg^{2+} , albumin 0.35%, and apyrase. (a) Represents the response of platelets from a normal control. (b) Represents the response of platelets from a patient with afibrinogenemia (Patient II). The percent release of serotonin is indicated beside the aggregation tracings. The concentration of the F(ab')_2 fragments of nonimmune IgG (F(ab')_2 NI) was 150 $\mu\text{g/mL}$; the concentration of the F(ab')_2 fragments of an antibody to fibrinogen (F(ab')_2 AF) was 100 $\mu\text{g/mL}$.

combination of inhibitors was more effective in deaggregating the afibrinogenemic platelets than the control platelets.

DISCUSSION

The results from these studies show that fibrinogen in the ambient fluid is not necessary for ADP-induced platelet aggregation, although fibrinogen greatly enhances the extent of aggregation. This is in agreement with the results of Soria et al.¹

In citrated PRP from an afibrinogenemic patient and with suspensions of either normal or afibrinogenemic platelets without added fibrinogen, the formation of the small aggregates induced by ADP is not inhibited by F(ab')_2 fragments of an antibody to fibrinogen, although these fragments block the enhancement of aggregation produced by adding fibrinogen to the suspending fluid. The aggregation that occurs

without added fibrinogen is blocked by an antibody (10E5) to glycoprotein IIb/IIIa, indicating that the receptor for adhesive proteins is involved in this response. Thus there is a component of platelet aggregation that is not dependent on plasma proteins such as fibrinogen but is dependent on glycoprotein IIb/IIIa.

Washed human platelets stimulated by ADP in the presence of physiologic concentrations of Ca^{2+} release little or no serotonin from their amine storage granules and only about 4 μg of fibrinogen per 10^9 platelets from the α granules in response to 10 $\mu\text{mol/L}$ ADP.²⁸ The afibrinogenemic platelets had approximately 10 μg of fibrinogen per 10^9 platelets. If this were in the granules and released in proportion to the release from normal platelets, the concentration of fibrinogen in the ambient fluid would be less than 0.05 $\mu\text{g/mL}$. This is insufficient to cause a detectable enhancement of ADP-induced aggregation, for which at least 3 $\mu\text{g/mL}$ is necessary. Furthermore, the F(ab')_2 fragments of an antibody to fibrinogen did not inhibit the response to ADP. However, proteins other than fibrinogen, including thrombospondin, fibronectin, and von Willebrand factor (vWF) may have been released. Since fibronectin has not been found to support ADP-induced aggregation,^{45,46} it is unlikely to be involved in the aggregation observed. Recently de Marco and his associates⁴⁷ reported that addition of vWF to afibrinogenemic citrated PRP supports ADP-induced aggregation of afibrinogenemic platelets. However, the concentrations of vWF required (up to 60 $\mu\text{g/mL}$) were higher than would be present in plasma even if all the platelet vWF were released. The observation that the antibody LJP5, an antibody to glycoprotein IIb/IIIa that blocks the binding of vWF but not of fibrinogen to IIb/IIIa, inhibits platelet aggregation in response to ADP and collagen in afibrinogenemic citrated PRP is in favor of vWF being involved.⁴⁷ However, the concentration of vWF would be negligible in suspensions of washed human platelets in a medium containing 2 mmol/L Ca^{2+} , in which ADP causes very little release of α -granule contents; in addition, vWF does not support ADP-induced aggregation in this medium.⁴⁸

The response of afibrinogenemic platelets to thrombin (0.2 to 1 U/mL) or PAF (0.25 $\mu\text{mol/L}$) is practically indistinguishable from the response of normal platelets, indicating that released fibrinogen plays little part in the formation of platelet aggregates induced by these agonists. With collagen or sodium arachidonate the lack of releasable fibrinogen may contribute to the diminished aggregation response. One could also speculate that fibrinogen plays a greater part in aggregation that is largely dependent on thromboxane A_2 ; thrombin and PAF can act through pathways that are largely independent of thromboxane A_2 .⁴⁹⁻⁵¹ The finding that an antibody to fibrinogen did not inhibit platelet aggregation caused by 0.2 to 1 U/mL thrombin is in keeping with the observations of Legrand et al.³⁰ and raises the possibility, as proposed by Soria et al.,¹ of there being fibrinogen-independent mechanisms of platelet aggregation when platelets are stimulated with thrombin, and possibly with PAF.

We have previously shown that ADP-induced aggregation of human platelets is followed by rapid deaggregation if the release reaction does not occur.³⁴ Fibrinogen binding is

Fig 7. Effect of EDTA (2.5 mmol/L) and chymotrypsin (CHYM; 10 U/mL) on deaggregation of suspensions of washed platelets from a control subject and patient II, with afibrinogenemia. The platelets were aggregated by thrombin (1 U/mL). Hirudin (10 U/mL) was added to neutralize the thrombin two minutes after the thrombin addition, and chymotrypsin and EDTA were added with the hirudin.

associated with aggregation, and fibrinogen is lost from the surface of the platelets when they deaggregate.^{12,34} However, when the release reaction has taken place, agents such as PGE₁ or EDTA do not cause deaggregation, although they displace most of the bound fibrinogen (these agents do cause rapid reversal of ADP-induced aggregation under conditions in which the release reaction does not occur).³⁴ It was possible to study the role of fibrinogen in forming stable platelet aggregates by comparing the susceptibility of the afibrinogenemic platelets and normal platelets to deaggregation after thrombin stimulation. Since the rate at which platelets from normal and afibrinogenemic subjects deaggregated was similar, it seems reasonable to conclude that fibrinogen is not necessary for the formation of stable platelet aggregates when the platelet-release reaction has occurred. This is supported by the observation of Turitto and his associates³¹ who showed that large, stable, platelet aggregates

formed on the subendothelium of rabbit aorta exposed to native afibrinogenemic blood in a Baumgartner flow chamber.

Thus ADP-induced aggregation can occur to a small extent without the presence of fibrinogen, but it is greatly enhanced by the addition of fibrinogen. Furthermore, with agonists that cause the release reaction, enhancement by fibrinogen is seen only with low concentrations of the agonist, and fibrinogen is not required to stabilize the platelet aggregates that form under these conditions.

ACKNOWLEDGMENT

The technical assistance of M.A. Guccione, K.M. O'Brien, and D.W. Perry is gratefully acknowledged. The antibody to glycoprotein IIb/IIIa (10E5) was a generous gift from Dr Barry Collier, Stony Brook, NY.

HLA Associations With Leukemia

By Mortimer M. Bortin, Joseph D'Amato, Fritz H. Bach, Alfred A. Rimm, and Jon J. van Rood

Frequencies of 35 HLA A, B, C, and DR antigens were determined in 1,834 leukemic Caucasoids to evaluate possible associations between HLA and leukemia. In comparison with the frequencies of HLA antigens in published controls, the frequency of Cw3 was significantly higher in patients with acute lymphoblastic leukemia (relative risk = 2.64, $P < 0.0002$), acute myelogenous leukemia (relative risk = 1.92, $P < 0.0007$), and chronic myelogenous leukemia (relative risk = 2.07, $P < 0.002$; P values adjusted for multiple comparisons). The frequency of Cw4 was elevated in patients with acute lymphoblastic leukemia (relative risk = 2.01, $P < 0.0003$), acute myelogenous leukemia

(relative risk = 2.06, $P < 0.0002$), and chronic myelogenous leukemia (relative risk = 2.14, $P < 0.0008$). The frequency of Aw19 was significantly decreased in patients with acute myelogenous leukemia (relative risk = 0.68, $P < 0.01$) and chronic myelogenous leukemia (relative risk = 0.59, $P < 0.005$). None of the other 32 HLA antigens investigated had a statistically significant association with leukemia. The data suggest that Cw3 and Cw4 may be markers for leukemia susceptibility genes, while Aw19 may be a marker for decreased susceptibility to leukemia.

IN 1930 Fisher¹ proposed that selective interactions between genes might favor their linkage. Darlington and Mather² extended this idea and introduced the term "supergene" for groups of linked genes that are inherited *en bloc*. Overviews of the HLA supergene were published by Ceppellini,³ Bach and van Rood,⁴ Bodmer,⁵ and Bach.⁶ The biological importance of supergenes is emphasized by the fact that they are found in all vertebrate species that have been studied. The homology between the major histocompatibility complex (MHC) in different species supports the hypothesis that the MHC has been conserved throughout phylogeny because it confers important biological advantages on the species.⁷⁻¹⁰

The observation by Lilly et al¹¹ that increased or decreased susceptibility of mice to Gross virus-induced leukemia was linked to H-2^k and H-2^b respectively prompted Amiel¹² in 1967 to search for associations between histocompatibility antigens and pathologic conditions in humans. He reported a significant association for HLA B5 in patients with Hodgkin's disease.¹² Since then numerous studies investigated HLA associations with disease.¹³⁻¹⁵

In 1984 we reported the results of analyses investigating HLA associations with leukemia in 1,009 leukemia patients¹⁶ (hereafter referred to as "initial series"). We found a statistically significant increase in the frequency of Cw3 and Cw4 in patients with acute lymphoblastic leukemia (ALL) and of Cw4 in patients with acute myelogenous leukemia (AML). An additional 825 leukemia patients have now been studied ("current series"), and the results from these patients and the combined series are presented here.

PATIENTS AND METHODS

Patients. Detailed information regarding 1,834 North American and European Caucasoid patients treated with chemoradiotherapy and bone marrow transplantation (BMT) for leukemia was reported to the International Bone Marrow Transplant Registry. Transplants were performed between 1969 and 1985 by 96 BMT teams worldwide. The diseases studied were ALL, AML, and chronic myelogenous leukemia (CML; Table 1). Patients' median age was 21.4 years (range 0.6 to 59 years), and 55% were males. The median interval from diagnosis to transplantation was 9 months (range 0.3 to 144 months). At the time of transplantation 47% of the patients were in first remission or chronic phase, 20% in second remission, and the disease was more advanced in 33%. Chemotherapy failed to induce a first remission in 5% of the patients with acute leukemia.

Antigenic splits were converted to their equivalent broad specificities because many of the splits were not defined in the earlier years of this study. Data for 35 HLA antigens were available for investigation: eight HLA A antigens (1,2,3,9,10,11,w19,28), 15 HLA B antigens (5,7,8,12,13,14,15,16,17,18,21,w22,27,35,40), six HLA C antigens (w1,w2,w3,w4,w5,w6), and six HLA DR antigens (1,2,3,4,5,7). Estimates of the frequency of DRw6 in North American and European Caucasoid controls were not thought to be reliable, and this antigen was excluded from analysis. Data were available to analyze the frequency of HLA A in 1,834 patients, B in 1,801 patients, C in 783 patients, and DR in 709 patients.

HLA antigen frequencies for the control series of North American and European Caucasoids were obtained from Tables 6 through 9 in Baur and Danilovs¹⁷ population analysis from the Eighth International Histocompatibility Workshop.

Statistical analysis. The extensive polymorphism of HLA not only provides a large number of markers to be tested for possible associations with diseases but also presents problems in interpretation of results. The main problem is that the performance of large numbers of statistical comparisons increases the probability that apparent differences between two groups may have occurred solely by chance. Svejgaard et al¹⁸ discussed this problem and suggested several methods to help resolve it.

Table 1. Distribution of Patients by Disease

Disease	Initial Series	Current Series	Total
ALL	423	304	727
AML	383	282	665
CML	203	239	442
Total	1,009	825	1,834

Haldane's modification¹⁹ of Woolf's method²⁰ was used to assess the significance of the differences in the antigen distributions in the control v the leukemia populations. Multiplex testing for heterogeneity in a single locus or multiple loci was performed by summing the chi squares provided by the Woolf-Haldane analysis. That value is itself a chi square with degrees of freedom equal to the total number of antigens in the locus or loci.²¹ Corrected *P* values were derived by taking into account the 35 antigens that were tested using the method of Edwards.²² Only corrected *P* values are presented.

Initially HLA antigen frequencies from the 258 North American and the 567 European Caucasoids from the current series were tested independently against their respective controls. Comparisons were then made with the HLA antigen frequencies found in the 628 North American and 381 European Caucasoids from the initial series. This strategy was used because it would be most unlikely that the same association would be observed by chance alone in all four subsets. All four subsets were combined for an overall analysis.

RESULTS

Multiplex testing disclosed no significant heterogeneity in the distribution of HLA A, B, C, and DR antigens between the North American and European patients in the initial or current series. In particular there were no significant differences for the Aw19, Cw3, and Cw4 antigens. The distribution of the Aw19, Cw3, and Cw4 antigens in the North American and European control populations also did not differ significantly.

Of the 35 HLA antigens studied, only Aw19, Cw3, and Cw4 had significant associations with leukemia in general, ie, the combined diseases ALL, AML, and CML (Table 2). Compared with controls, Aw19 had a lower frequency and decreased relative risk in all four subsets of patients; the pooled data had a frequency of 23% v 30% for controls with a relative risk of 0.71 and a *P* value < 0.0006. Both Cw3 and Cw4 had consistently elevated frequencies in all four subsets in comparison with controls, and the relative risks of 2.20 and 2.06 respectively for the pooled data were highly significant (*P* < 0.00001).

Shown in Table 3 are the relative risks and significance levels for Aw19, Cw3, and Cw4 in the initial, current, and

combined series for ALL, AML, and CML. For the Aw19 antigen, note that the relative risk was consistently below 1.0 in each of the North American and European subsets and for each of the diseases studied, but in none of the 12 subsets was statistical significance observed. It was not until the data were pooled, with a resultant increase in the power of the test, that statistically significant lower frequencies for Aw19 were found both for the 665 patients with AML and the 442 patients with CML. In the pooled data from 727 patients with ALL, the frequency of Aw19 was lower than controls, but the level was not statistically significant.

The frequency for Cw3 was consistently elevated for patients with ALL, AML, and CML but was statistically significant in only three of four ALL, in one of four AML, and in one of four CML subsets (Table 3). When the data were pooled, the power of the test increased, and the frequency of Cw3 was significantly increased for each of the diseases. Similarly, the frequency of Cw4 was consistently elevated for all 12 subsets of patients but was statistically significant in only two subsets of AML patients. The combined data indicate that Cw4 has a significantly increased frequency for ALL, AML, and CML.

In the combined series there were 72 patients with ALL or AML in whom complete remission was not attained following induction chemotherapy. They were considered to be refractory to chemotherapy. To determine whether Aw19, Cw3, or Cw4 might be associated with responsiveness to chemotherapy in leukemia patients rather than leukemia per se, the frequencies of these antigens were analyzed in the 1,320 patients with acute leukemia who had responded to chemotherapy and the 72 patients who had not. No statistically significant heterogeneity was found; chi squares were 1.08 for Aw19; 0.03 for Cw3; and 0.01 for Cw4. Among the patients who had not responded to chemotherapy, the frequency of Aw19 was not significantly different from patients who had responded; 31% v 30% respectively. The frequency of Cw3 of nonresponders, however, was increased; 36% v 20% for controls (uncorrected *P* = 0.012), as was the frequency of Cw4; 40% v 22% for controls (uncorrected *P* = 0.005).

DISCUSSION

This investigation of 1,834 patients with leukemia disclosed highly significant associations between HLA and the risk of leukemia. In comparison with healthy controls, frequencies of Cw3 and Cw4 were increased (relative risk > 2.0, *P* < 0.00001), and the frequency of Aw19 was decreased

(relative risk <0.72, $P < 0.0006$). These findings confirm and extend our previous report investigating HLA association with leukemia.¹⁶ Frequencies for the 32 other A, B, C, and DR antigens studied were not significantly different from controls.

Most studies of HLA associations with leukemia have focused on the HLA A, B, or D/DR loci.²³⁻⁴¹ The findings have been inconsistent, and no strong associations between these loci and leukemia have been reported (Table 4). In particular, to the best of our knowledge, associations between HLA C and leukemia were not reported prior to or since our initial study.¹⁶ De Jongh et al²⁶ conducted the only study known to us in which HLA C associations with leukemia were investigated. They found no significant difference in HLA C antigen frequency between controls and a group of 44 children with ALL. The discrepancy between their results and ours may have been due to the low power of the test in their study.

The pooled data showed that Aw19 had a significantly lower frequency among leukemia patients in general. In our initial study the lower frequency of Aw19 in leukemia patients was uncertain because it had only borderline significance (corrected $P = 0.047$) in the North American subset of 628 patients and was not significant in the 381 European patients.¹⁶ With the group size increased from 1,009 to 1,834 leukemia patients, it now seems clear that the frequency of Aw19 is indeed decreased in leukemia patients. The frequency of Aw19 was significantly reduced in AML ($P < 0.01$) and CML ($P < 0.005$). Although not statistically significant in ALL, it should be noted that the relative risk associated with Aw19 was consistently lower than 1.0 in all four subsets of ALL patients (Table 3). In one study of 60 patients with ALL, a decreased frequency of Aw19 (uncorrected $P < 0.05$) was reported by Klouda et al.³⁵ It is possible that when additional patients with ALL become available for study, Aw19 may also prove to be associated with a reduced risk for this disease.

The strong positive association of Cw3 and Cw4 with leukemia supports the possibility that these antigens, or the genes encoding them, are, or are closely linked with, possible susceptibility genes. An increased relative risk of leukemia has been observed in the siblings of leukemia patients,^{42,43} but the mechanism is not known. Based on the findings reported

here, it is possible that the mechanism may be due in part to an increased frequency of Cw3 or Cw4 in siblings of leukemia patients. Studies of HLA C in instances of familial leukemia are encouraged. Another possibility, suggested by other studies, is that Aw19, Cw3, and Cw4 may be markers coding for immune responsiveness to putative leukemia viruses; DeVries et al⁴⁴ found a significant association between Cw3 and low in vitro responses to vaccinia virus. Our data show no association between Aw19, Cw3, or Cw4 and responsiveness to chemotherapy in leukemia patients.

The reader is cautioned that our findings may not be representative of all leukemia patients because of several unavoidable biases in the database of the International Bone Marrow Transplant Registry. For example, most teams do not perform BMTs on older patients. As a consequence, almost all patients in this study were less than 50 years of age, and our findings may not apply to older leukemia patients. The 95% remission-induction rate in our cases with acute leukemia is higher than most reports of nontransplanted patients, especially those with AML. All patients reported here survived long enough to undergo BMT. It is likely that some patients for whom BMT was planned died before the plan could be implemented. It is possible that patients with especially virulent forms of leukemia or, as suggested by Rogentine et al,³³ some less hardy patients did not survive long enough to be transplanted and thus were not available to us for study. Other interpretations are possible. Furthermore, HLA data for patients with chronic lymphocytic leukemia were not available to us for analysis, and it is not known whether the findings reported here also apply to these patients or to non-Caucasoids. Studies of HLA associations with morphological, immunologic, and cytogenetic subtypes of leukemia will be undertaken in the future with an expanded database.

The positive and negative associations with leukemia we found with relative risks ranging from 2.64 to 0.59, while highly significant, are weak in comparison with those described in some other studies showing significant associations between HLA and disease.¹³⁻¹⁵ The extremes, according to Svejgaard et al,¹⁴ are the positive association between B27 and ankylosing spondylitis, with a relative risk of 87.4, and the negative association between DR2 and insulin-dependent diabetes, with a relative risk of 0.2. The analyses presented

‡This report.

here clearly show the desirability of a large database in studies investigating HLA associations with disease when there is in fact a relationship but it is not strong. For example, in Table 3, although a trend was present, Aw19 was not significantly associated with AML or CML in any of the subsets. Only when group sizes in the combined series were

665 (AML) and 442 (CML) did statistically significant associations become evident. Similarly, Cw4 was not statistically significant in any of the ALL or CML subsets; using pooled data from the combined series demonstrated highly significant associations with each disease. Another problem with relatively small group sizes is demonstrated by those

instances when significant associations were found in some subsets but not in others (Table 3). It is clear from the data shown in Table 4 that inadequate group sizes account for many of the conflicting reports in the literature describing the presence or absence of HLA associations with leukemia.

The increased frequency of Cw3 and Cw4 and decreased frequency of Aw19 in leukemia patients provides strong evidence that the HLA supergene, as H-2 in the mouse, may play a role in increased and decreased susceptibility to leukemia. Although it is far from clear that the mechanism for the association in mouse and man is similar, until now the parallel has been elusive.

It is generally believed that HLA antigens influence the T lymphocyte repertoire. We found that the risk of leukemia is significantly increased in individuals with Cw3 or Cw4. It seems likely that these people will have a T cell repertoire that is different from individuals who are negative for Cw3 and Cw4. This simply means that Cw3 and Cw4 antigens are immune response gene products. It does not answer the question of how these immune response genes confer low responsiveness against a putative leukemia-inducing agent. Our data imply that individuals who have neither Cw3 nor Cw4 are better able to resist leukemia than those who are positive. This remains purely speculative because there are no available tests to investigate this hypothesis.

The fundamental importance of this study is not that Cw3 and Cw4 were found to have significant associations with leukemia but rather that HLA C genes, or genes closely linked with HLA C, have hitherto unrecognized properties. Whether HLA C also will be found to be associated with other malignant and nonmalignant diseases remains to be determined.

ACKNOWLEDGMENT

The authors thank D'Etta Koser, Sharon Gurgul, and Todd Siefert for help with data analysis and Karen Witkowski for help in preparation of the manuscript.

APPENDIX

This 32nd report from the International Bone Marrow Transplant Registry was prepared for the Advisory Committee: R.P. Gale, Los Angeles (Chairman); F.H. Bach, Minneapolis; A.J. Barrett, London; D.W. van Bekkum, Rijswijk; J.C. Biggs, Sydney; K.G. Blume, Los Angeles; M.M. Bortin, Milwaukee; K.A. Dicke, Houston; E. Gluckman, Paris; J.M. Goldman, London; R.A. Good, St. Petersburg; R. Hong, Madison; R.H. Herzig, Cleveland; J.H. Kersey, Minneapolis; H.J. Kolb, Munich; A.M. Marmont, Genoa; T. Masaoka, Osaka; H.A. Messner, Toronto; R.J. O'Reilly, New York; R.L. Powles, London; A.A. Rimm, Milwaukee; O. Ringden, Huddinge; J.J. van Rood, C. Rozman, Barcelona; B. Speck, Basel; R.S. Weiner, Gainesville; and F.E. Zwaan, Leiden.

Institutions contributing patient data for this report are listed below: Academisch Ziekenhuis-Leiden, Leiden, The Netherlands; Academisch Ziekenhuis St. Raphael, Leuven, Belgium; Alta Bates Hospital, Berkeley, CA; Bishop Clarkson Memorial Hospital, Omaha; Bone Marrow Transplant Unit, Besconson, France; Case Western Reserve University Hospitals, Cleveland; Cattedra Di Immunologia Clinica, Rome, Italy; Centre Hospitalier Regional, Nancy,

Identification of Molecular Variants of p210^{bcr-abl} in Chronic Myelogenous Leukemia

By Razelle Kurzrock, William S. Kloetzer, Moshe Talpaz, Mark Blick, Ronald Walters, Ralph B. Arlinghaus, and Jordan U. Gutterman

The aberrant *abl* protein product of a chronic myelogenous leukemia (CML) blast crisis cell line (K562) and of five Philadelphia chromosome-positive CML patients in blast crisis were analyzed by an immune complex kinase assay using two antipeptide sera generated against the hydrophilic domain of *v-abl* and a region within the third exon of the breakpoint cluster region (*bcr*) respectively. Both the anti-*abl* and anti-*bcr* sera detected a 210 kd band in extracts derived from K562 cells and from two CML patients with myeloid blast crisis. p210 was detected by the anti-*abl* but not the anti-*bcr* sera in three CML patients

A SHORTENED chromosome 22, designated the Philadelphia (Ph) chromosome, is found in the majority of patients with chronic myelogenous leukemia (CML) and is considered the cytogenetic hallmark of the disease.^{1,2} This chromosomal anomaly is usually the result of a reciprocal translocation between chromosomes 9 and 22, (t[9;22](q34;q11)).² The breakpoints on chromosome 22 occur within a 5.8 kb segment of DNA, termed the breakpoint cluster region or *bcr*.^{3,4} A crucial event in the Ph translocation is the transfer of the *c-abl* oncogene from its normal residence on chromosome 9 to chromosome 22 so that *bcr* and *c-abl* sequences are juxtaposed in a head-to-tail configuration with *bcr* closer to the centromere.^{5,6} The resulting messenger RNA (mRNA) is a hybrid of 5' *bcr* sequences and a truncated *c-abl* gene lacking the first exon.⁶ This chimeric *bcr-abl* mRNA encodes a novel 210,000 MW protein, whereas the normal *c-abl* gene is expressed as a 145,000 MW protein.⁷⁻⁹ Therefore p210^{bcr-abl} represents a unique cancer-specific marker.

The Abelson murine leukemia virus encoded p160^{v-abl} has tyrosine-specific protein kinase activity that is closely associated with its ability to transform cells.¹⁰⁻¹³ Although both the aberrant p210^{bcr-abl} and the normal p145^{c-abl} also have an associated tyrosine-protein-kinase activity, p160^{v-abl} and p210^{bcr-abl} utilize themselves as substrates differently than p145^{c-abl} in vitro.⁹ The high specificity and altered autophosphorylation properties of p210^{bcr-abl} strongly implicate a critical role for this molecule in the pathogenesis of CML.

In this report we have used anti-*abl* and anti-*bcr* (to exon 3) peptide sera in an immune complex kinase assay (ICKA) to investigate p210^{bcr-abl} expression in Ph-positive CML. We demonstrate that a variable number of *bcr* exons may be incorporated into p210^{bcr-abl} and that the resulting heterogeneous products retain enzymatic activity as protein kinases.

MATERIALS AND METHODS

Antisera. Antiserum was made against a peptide representing the predicted hydrophilic *v-abl* sequence 389-403 (DEVEKELGKRGTRGG-C) and a region within *bcr* exon 3 (DDESPGLYGLNV-C),⁶ as described by Kloetzer et al.⁷ The peptide was synthesized using solid-phase synthesis. Cysteine residues were added to the carboxyl termini during synthesis for MBS cross-linking through free sulfhydryl groups to the carrier protein keyhole limpet hemocyanin. Antigen was prepared by emulsifying at 1:1

with myeloid (one patient) and lymphoid (two patients) blast crisis, indicating the absence of *bcr* exon 3 in this protein. Southern blot analysis on DNA derived from one of the patients in the latter group was consistent with the break on chromosome 22 occurring 5' to *bcr* exon 3. Our observations demonstrate that the Philadelphia translocation results in the generation of a chimeric *bcr-abl* protein with at least two molecular variants, both of which are enzymatically active as protein kinases.

© 1987 by Grune & Stratton, Inc.

ratios 0.2 mg of cross-linked peptide in Dulbecco's phosphate-buffered saline (PBS) with 1.5 mL of complete Freund's adjuvant. Subcutaneous (SC) injections of rabbits were administered at multiple sites. Three booster injections of antigen suspended in incomplete Freund's adjuvant were given at 2-week intervals.

Immune complex kinase assays (ICKAs). Blood samples were obtained from patients after informed consent. The blood was prepared for ICKAs by treating with 5 volumes of 1.22% ammonium oxalate to lyse red blood cells (RBCs) and Ficoll-Hypaque (FH) gradient centrifugation to enrich for immature cells. K562 cells (Ph-positive CML erythroid blast crisis cell line)^{14,15} were also assayed. Each sample was divided into four aliquots of 5×10^7 cells. Each aliquot was disrupted with 1 mL of lysis buffer (1% Triton X-100, 5 mmol/L EDTA, 100 mmol/L NaCl, 5 mmol/L phenylmethylsulfonylfluoride, 100 KIU/mL Trasylol, in 10 mmol/L sodium phosphate, pH 7.5) with 20 strokes in a tight-fitting Wheaton homogenizer. Lysates were subjected to a 10,000 g centrifugation for ten minutes at 4°C. The supernatant from the four aliquots was then incubated with (1) 5 μ L of anti-*abl*389-403 serum, (2) 5 μ L of anti-*abl*389-403 serum and 5 μ L of *abl*389-403 peptide (3) 5 μ L of anti-*bcr*3 serum, or (4) 5 μ L of anti-*bcr*3 serum and 5 μ L of *bcr*3 peptide. Concentration of the peptide solution was 1 mg/mL H₂O. Incubation was carried out for one hour on ice. The resulting immune complexes were then precipitated by incubation with 10 μ L of Pansorbin for 20 minutes on ice. Immunoprecipitates were washed twice with wash buffer (0.1% Triton X-100, 150 mmol/L NaCl, in 10 mmol/L sodium phosphate, pH 7.5). The pellets were drained, resuspended in 50 μ L of 20 mmol/L HEPES (pH 7.0), containing 0.1% Triton X-100, and 150 mmol/L NaCl, and then reacted with

50 μ L of a mixture containing 5 μ Ci [gamma- ^{32} P] ATP (50 Ci/mmol), 20 mmol/L $MnCl_2$, 0.1% Triton X-100 in 20 mmol/L HEPES (pH 7.0) for ten minutes on ice. The reaction was terminated by addition of 3 mL of buffer containing 1% Triton X-100, 0.1% sodium dodecyl sulfate (SDS), 0.5% DOC, 100 mmol/L NaCl, 5 mmol/L EDTA, in 10 mmol/L sodium phosphate, pH 7.5. The immune complexes were washed twice with the above buffer and then prepared for electrophoresis according to Laemmli.¹⁶ Phosphoproteins were electrophoretically resolved according to mol wt on an 8% SDS polyacrylamide gel and sized with prestained mol wt markers. The gel was exposed overnight on Kodak XAR-5 film.

Southern blotting. DNA was prepared by cell lysis, proteinase K digestion, phenol/chloroform extraction, and ethanol precipitation as previously described.¹⁷ Twenty micrograms of genomic DNA was digested with BglIII and Bam HI restriction endonucleases (2 U/ μ g of DNA) in conditions recommended by the supplier (International Biotechnologies, Inc, New Haven, CT), size fractionated by electrophoresis in a 0.8% agarose gel, denatured and transferred to nitrocellulose as described by Southern.¹⁸ A 3', 1.2kb *bcr* (HindIII-BglIII) plasmid probe (Oncogene Science, Inc, Mineola, NY) was used.³ The probe was nick-translated to a specific activity of 1 to 2×10^8 cpm/ μ g of DNA. Hybridization was carried out overnight at 42°C in the presence of 10% dextran sulfate. The filters were then washed twice at 60°C for 30 min/wash in $0.1 \times$ standard saline citrate (SSC) ($1 \times$ SSC = 0.15 mol/L sodium chloride/0.015 mol/L sodium citrate, pH 7) containing 0.1% SDS, air dried, and autoradiographed.

RESULTS

A 210,000 MW *abl* protein was detected in extracts of K562 cells using anti-*abl*389-403 serum in an ICKA (Fig 1, lane 1), a result consistent with previous reports.⁷⁻⁹ The 190,000 MW protein seen on the gels is thought to be either a proteolytic fragment of p210 or a second translation product of the *bcr-abl* gene. The 210,000 and 190,000 MW proteins were determined to be *abl* specific, since these proteins were not detected in assays in which the reactivity of the anti-*abl*389-403 serum was blocked by prior addition of excess *abl*389-403 peptide (Fig 1, lane 2). Addition of an unrelated peptide did not change the reactivity of anti-*abl*389-403 serum with p210 or p190 (Fig 1, lane 5), demonstrating that the blocking observed after addition of cognate peptide is not due to nonspecific competition. Using identical assay conditions, p210 was also detected in K562 cell extracts when the anti-*bcr*3 serum was used (Fig 1, lane 3), indicating that

p210 consists of both *bcr* and *c-abl* sequences. The incorporation of *bcr* exon 3 in K562 p210^{*bcr-abl*} is supported by the detailed investigations of Shtivelman et al,⁶ indicating that the RNA junction point in the *bcr-abl* transcript derived from K562 cells includes the third *bcr* exon.

Fresh cells from five CML patients, designated A, B, C, D, and E, were available for ICKA. Patients A, D, and E had myeloid blast crisis; patients B and C, lymphoid blast crisis. Examination of cell extracts derived from patients A and E revealed results that were similar to those found in K562 cells: p210 was expressed as an enzymatically active protein kinase and could be detected by both anti-*abl*389-403 and anti-*bcr*3 sera (Fig 1, lanes 15-22). In contrast, anti-*bcr*3 serum was not able to detect p210^{*bcr-abl*} protein kinase activity in cell extracts derived from CML patients B, C, and D (Fig 1, lanes 8 and 9, 13 and 14, 25 and 26), even though this protein is expressed and enzymatically active as a protein kinase, as demonstrated by its detection by anti-*abl*389-403 in the ICKA (Fig 1, lanes 6 and 7, 11 and 12, 23 and 24). The faint 210 kd band detected in CML patient B by the anti-*bcr*3 serum (Fig 1, lane 8) represents nonspecific background phosphorylation, as demonstrated by the failure of this band to be blocked by cognate peptide (Fig 1, lane 9) and by the detection of a similar faint band by preimmune rabbit serum (Fig 1, lane 10). Our results demonstrate the existence of two molecular variants of p210^{*bcr-abl*}—*bcr*(3):*abl* and *bcr*(-3):*abl*—in different CML patients.

Southern blot analysis revealed rearrangement in *bcr* in both BglIII and BamHI digested DNA from patient A (Fig 2, lane 3). These data are consistent with the inclusion of exon 3 of *bcr* in the expressed p210^{*bcr-abl*} of this patient (Fig 3). Rearrangement in *bcr* was observed in BglIII but not BamHI digested DNA from patient B (Fig 2, lane 1). Since the BamHI restriction site is located proximal to exon 3 of *bcr* (Fig 3), the break on chromosome 22 in patient B must occur 5' to exon 3. Therefore the results obtained from Southern blot analysis are consistent with the absence of exon 3 of *bcr* in the p210^{*bcr-abl*} derived from patient B, as demonstrated by ICKA. Differences in the intensity of bands from lane to lane were similar when the filters shown in Fig 2 were reprobed with a beta-actin cDNA probe (data not shown), indicating that these differences reflected variations in the amount of DNA in each lane.

DISCUSSION

The N-terminal replacement of *c-abl* by *bcr* sequences in the 210,000 MW protein product of Ph-positive CML patients has been previously predicted by studies of the aberrant 8 kb *bcr-abl* mRNA found in these patients.^{6,19} In addition, Ben-Neriah et al²⁰ have recently demonstrated that p210 contains both *bcr* and *c-abl* sequences. Our data indicate that the Ph translocation results in the generation of at least two molecular variants of the *bcr-abl* protein. These variants differ in that they either contain or lack *bcr* exon 3—*bcr*(3):*abl* v *bcr*(-3):*abl*. They are generated as a result of the differing locations of the breaks on chromosome 22, which can occur both proximal and distal to the third exon of *bcr*. The absence of *bcr* exon 3 does not appreciably alter the size of the 210-kd *bcr-abl* protein, probably because this exon is small, consisting of only 25 amino acids.⁴ Our experiments also demonstrate that both *bcr-abl* variants are enzymatically active as phosphokinases, a property of potential fundamental importance for CML, since this enzymatic activity has been strongly implicated in the ability of several oncogenes and growth factor receptors to exert their effects.²¹

The clinical course of CML is characterized by the inevitable progression from an easily controlled benign phase to a terminal blast transformation phase²² in a time period

Fig 3. Restriction enzyme map of *bcr* (adapted from Heisterkamp et al⁴). Exons are indicated by vertical boxes below the map. The horizontal bar above the map shows the 1.2 kb HindIII-BglII *bcr* probe. Below the map the approximate positions of the breakpoints of Ph-positive CML patients A and B. ranging from several weeks to 23 years (median interval = 3.5 years).^{22,23} The blasts at the time of transformation usually display characteristics of myeloid lineage, although a minority of patients (about 30%) may develop a lymphoid blast crisis.²⁴ The factors influencing the morphology of the blasts and the length of time to the transformation stage remain unknown. Recent work has demonstrated that subtle alterations in oncogene configuration can be associated with phenotypic variations of a tumor, ie, distinct chromosomal 8 breakpoint sites relative to the *c-myc* oncogene are found in the endemic v sporadic forms of Burkitt's lymphoma.²⁵ Interestingly, two of three patients with the *bcr*(-3):*abl* protein variant demonstrated several unusual clinical features: a survival of 10 and 11 years respectively (seen in less than 5% of patients)²⁶ and a terminal lymphoid blast phase. Both patients with the *bcr*(3):*abl* protein showed a more typical clinical course, with a survival of 3 and 3.5 years respectively and a terminal blast crisis of myeloid lineage. Whether the absence of *bcr* exon 3 in the p210^{bcr-abl} product of some CML patients is related to long survival, and/or the development of a blast crisis of lymphoid lineage, or is merely fortuitous requires further investigation. Studies correlating the exact location of the breakpoint in *bcr* and the structure of p210^{bcr-abl} with clinical characteristics of a large series of CML patients are in progress and should help elucidate whether or not the generation of molecular variants of p210^{bcr-abl} is important in the malignant evolution of CML.

Pseudosickling of Hemoglobin Setif

By Samuel Charache, Eva Raik, David Holtzclaw, Patricia J. Hathaway, Elizabeth Powell, and Patricia Fleming

Hemoglobin Setif produces pseudosickling of red cells in vitro; the nature of the process and the conditions that "trigger" it are unknown. Studies of red cells, hemolysates, purified hemoglobin solutions, and artificial mixtures of Hb A and Setif suggest that pseudosickling is produced by intracellular crystallization of insoluble hemoglobin. Increased tonicity of the suspending medium accentuates the process, probably by causing a rise in intracellular

hemoglobin concentration. If precipitates from A/Setif mixtures are analyzed, they always contain Hb A, suggesting an unusual mechanism for the process. Despite the fact that osmolality in the renal medulla is similar to that which produces pseudosickling in vitro, carriers do not have renal dysfunction of the type found in patients with sickle cell disease.

© 1987 by Grune & Stratton, Inc.

PSEUDOSICKLING of red cells containing Hb Setif ($\alpha 94 \text{ Asp} \rightarrow \text{Tyr}$) was first described by Drupt et al^{1,2} and has been reported by others.³ The appearance of deformed cells does not resemble either truly sickled cells or the sickled cells of deer and other species: their contorted, elongated form gives an impression of twisted rods rather than the anisotropic domains characteristic of classic sickling disorders. Like the red cells of deer and unlike true sickle cells, they have not been found in vivo, and they have not been recognized to produce a clinical disorder.

Conditions required for deformation of Hb Setif-containing red cells have not been defined. Drupt found that incubation of a small volume of blood (50 μL) in an empty 5-mL plastic tube at 37°C yielded optimal results,⁴ and he and his coworkers showed that the phenomenon requires oxyhemoglobin, not deoxyhemoglobin.² They suggested that dehydration of red cells might be involved in sickling, and Raik et al³ showed that sickling could not be related to variations in the salt composition of isotonic suspending solutions. The requirement for oxyhemoglobin may perhaps be explained by the site of the amino acid substitution⁵: replacement of Asp $\alpha 94$ (G1) by tyrosine would be expected to disrupt a hydrogen bond that stabilizes the oxy, but not the deoxy, conformation of the hemoglobin molecule.⁶

If we are to truly understand the pathogenesis of sickle cell disease, the absence of clinical illness and of in vivo sickling in almost all persons with sickle cell trait is as important as their presence in patients with sickle cell anemia. Normal β^A globin chains, either in hybrid molecules ($\alpha_2\beta^A\beta^S$) or in homotetramers ($\alpha_2\beta_2^A$) can copolymerize with Hb S,⁷⁻¹⁰ and AS erythrocytes can sickle, but they usually do not at normal blood PO_2 , and most heterozygotes remain symptom free. Heterozygous carriers of Hb Setif are also symptom free¹¹⁻¹³; their freedom from more than minor hematologic abnormalities (see below) is usually attributed to the low proportion of the abnormal hemoglobin in their red cells (12% to 24%). Raik et al studied a compound heterozygote (II-1)³ with Setif/alpha and beta thalassemia, whose red cells contained 30% of the abnormal hemoglobin; he too showed neither vaso-occlusive crises nor hemolysis. To further characterize the behavior of red cells containing Hb Setif and to compare them with more familiar hemoglobinopathies, we have further defined the conditions required for pseudosickling. Suggestions are made concerning the nature of the process and the lack of clinical consequences.

PATIENTS

The compound heterozygote (FIK, II-1),³ his mother PEY, and his brother FER were studied. All were carriers of Hb Setif; FIK had

microcytic red cells (Coulter Counter) with target cells and hypochromia, as did his mother and brother to a lesser degree (Table 1), but Howell-Jolly bodies and siderocytes were not seen. The mother had been treated for menorrhagia and had had recurrent urinary tract infections with hematuria. Serum electrolytes, urea nitrogen, and creatinine were normal in all three patients, except for minimally elevated chloride in PEY (109 mmol/L). After overnight dehydration PEY was unable to concentrate her urine, but her sons were normal in this regard. Ophthalmologic examination (by Dr M. Hargrave) was normal in all three patients, except for a pigmented area in the temporal retina of FIK.

MATERIALS AND METHODS

For initial studies blood was obtained from the Setif/thalassemia compound heterozygote referred to earlier and a normal control. After collection in Sydney in ACD anticoagulant solution, the samples were shipped to Baltimore in ice and arrived within 48 hours with no evidence of hemolysis. Red cells were washed with 0.15 mol/L NaCl solution, gassed with carbon monoxide, and stored at -70°C until further use. Studies of sickling and oxygen affinity were done at Westmead Hospital, near Sydney, using blood collected in Na_2EDTA from three members of the affected family.

Pseudosickling was evaluated by incubating red cells in buffered potassium phosphate (4 to 5 mmol/L) or Tris HCl (0.01 mol/L) buffered NaCl or KCl solution for varying periods of time and at various temperatures. Osmolality was adjusted by alteration of NaCl or KCl concentration, and was measured with an Advanced Osmometer. After incubation, cells were fixed in 3.0% glutaraldehyde in phosphate buffered 0.15 mol/L NaCl solution pH 7.3. For estimating the proportion of deformed cells, samples were coded so that the observer did not know how they had been treated. All cells were counted by a single observer, and cells from different experiments (Table 2) were counted separately. Four hundred cells were counted and were considered as sickled only if they had the typical "sickled" shape (Fig 1). Crenated cells were also enumerated; it seemed likely that some of them represented transitional forms between discocytes and sickled forms, for their numbers decreased as

Table 1. Carriers of Hb Setif

Sex	Age	Hb (g/dL)	MCV (fl)	Hb Setif %	MCHSC g/dL		Hb A ₂ %	Hb F %	Osmolarity Urine/Serum (mosm/kg/H ₂ O)	
					370	459				
PEY	F	52	10.0	80	14.3	4.9	5.7	1.3	0.6	277/290
FIK	M	28	13.2	65	39.5	12.6	14.0	2.8	0.5	1081/291
FER	M	26	14.0	78	16.4	5.7	6.6	1.9	0.7	1092/283

Abbreviation: MCHSC, mean corpuscular hemoglobin Setif concentration in buffer of given osmolality, calculated from hemoglobin, microhematocrit value, and proportion of Hb Setif.

Urine and serum osmolality were measured after overnight abstention from water.

Proportions of Hb Setif and A₂ were measured by elution from strips of cellulose acetate after electrophoresis at pH 8.6; 1.0% A₂ was seen in sample from FIK; but no "split" A₂ was seen in samples from PEY or FER. The % Hb Setif in FIK is higher than previously reported; his MCHSC in isotonic buffer (285 mosm/kg H₂O) was approximately 10.2 g/dL.

the proportion of clearly sickled cells increased. Apparent differences in sickling properties from day to day (compare FER in Table 2) were more likely due to variation in the observer than in the red cells. Red cell indices for cells suspended in hypertonic buffer were based upon automated (Coulter Counter) hemoglobin and red cell determinations and microhematocrits centrifuged for 15 minutes. Centrifugation for longer periods did not result in greater packing of the red cells. Cells were considered oxygenated when studied in aerated buffers; for deoxygenation the buffer was equilibrated with nitrogen, added to a N₂ filled tube, a drop of red cell suspension was added, additional N₂ was blown over the surface, and the tube was capped.

For purification of Hb Setif, CO-equilibrated buffers and hemolysates were used. Fractions were separated by chromatography on diethyl aminoethyl (DEAE)-Sephadex¹⁴ checked for purity by electrophoresis at pH 8.6, rechromatographed if necessary, and concentrated by ultrafiltration through cellophane membranes after regassing with CO. Concentrated (5 to 10 g/dL) purified solutions of Hb A or Setif were stored under CO at -70°C. In an attempt to measure solubility, samples of Hbs A and Setif were further concentrated overnight by ultrafiltration. A precipitate formed only in samples of Hb Setif and was isolated by centrifugation. To estimate the solubility of Hb Setif, the hemoglobin concentration of the supernatant was measured. Since solvent conditions were uncertain after ultrafiltration, a small amount of buffer was added to the precipitate, the specimen was mixed and equilibrated for several hours, and

NOTE. Cells incubated at 23°C in 0.04 mol/L PO₄/NaCl buffer: 24 hours, pH 7.3; 459 mosm/kg, pH 7.3; two hours, 436-451 mosm/kg H₂O. See text for description of patients FIK, FER, and PEY.

Fig 1. Pseudosickling of Hb Setif-containing red cells. (A) Light microscopy, Nomarsky optics. (B, C) Scanning electron microscopy.

recentrifuged; the process was repeated once again, and hemoglobin concentrations of the supernatant fluids were also measured.

These experiments yielded relatively large crystals of Hb Setif, but attempts to estimate solubility of the abnormal hemoglobin yielded results that were erratic and unreproducible. More satisfactory measurements were obtained using a different technique. Concentrated specimens of purified hemoglobin A or Setif (5 to 10 g/dL) were dialyzed overnight at 5°C against 5 mmol/L potassium phosphate in 150 mmol/L KCl (pH 7.2 unless specified otherwise) saturated with carbon monoxide. Dialyzed solutions were diluted with buffer to a chosen hemoglobin concentration (usually 4 g/dL), centrifuged, and regassed with carbon monoxide. These solutions were added to Centricon-10 (Amicon Corporation, Scientific Systems Division, Danvers, MA) filters (10 kd nominal cutoff). Each concentrator was filled with 2 mL of hemoglobin and then centrifuged at 6,000 rpm (RCF = 4,340 g) in a Sorvall SS-34 rotor at 5 to 10°C. In most experiments, the centrifuge was stopped at five-minute intervals, the hemoglobin solutions above the filters were mixed, and centrifugation was resumed. At 15- to 20-minute intervals the hemoglobin solutions above the filters were removed from the concentrators and centrifuged at 10,000 rpm (RCF = 12,100 g) for ten minutes to sediment any precipitate. Supernatant fluid was decanted, a 15 to 25 µL sample was removed for measurement of hemoglobin concentration, and the remainder was returned to the concentrator and the process repeated until the volume of supernatant fluid was too small (about 0.2 mL) to be handled (typically, 6 or 7 cycles). In such experiments if the supernatant hemoglobin concentration remained more or less constant with repeated centrifugation (eg, Hb Setif in Fig 2B), that concentration was considered as the "solubility" of the hemoglobins. If the concentration rose continuously, one could only say that "solubility" exceeded the final concentration achieved. If one started with a dilute solution (Fig 2A), the final concentration achieved might well be less than the solubility.

For experiments involving deoxyhemoglobin, carboxyhemoglobin

Fig 2. Centrifugation of purified solutions of Hb A and Setif in 0.15 mol/L KCl, 0.005 mol/L PO_4 , pH 7.2, over Centricon filters. (A) Initial concentration 0.5 g/dL; (B) Initial concentration 4 to 5 g/dL.

was first converted to the oxy form by placing it in an IL 237 Tonometer (Instrumentation Laboratories, Inc, Lexington, MA) and exposing it to oxygen and light from a 200-watt bulb for 30 minutes at 5°C. The oxyhemoglobin was then converted to the deoxy form by an additional 30-minute exposure to nitrogen. Most of the sample became deoxygenated (84% to 92%) with negligible methemoglobin production (<2.4%). Each concentrator was filled with 1.5 mL of the deoxygenated solution, a few crystals of Na dithionite were added, and the solution was overlaid with a small amount of mineral oil. The concentrators had been preflushed with nitrogen, and they were enclosed in 50-mL centrifuge tubes that also had been flushed with nitrogen. Centrifugation of the concentrators was not interpreted at five-minute intervals but was allowed to proceed continuously for 40 minutes.

To study interaction between Hb A and Setif, samples of the purified carboxyhemoglobins were mixed to give proportions of Hb Setif from 10% to 50%, and were subjected to ultrafiltration, essentially as described above. The proportions of Hb A and Setif in the supernatants were determined after elution from cellulose acetate strips. Somewhat higher values were obtained by densitometry after electrophoresis on agar gel.¹⁵

Hemoglobin concentrations were determined by conversion to cyanmethemoglobin with Drabkin's reagent. Percentages of oxyhemoglobin, carboxyhemoglobin, and methemoglobin were determined using an IL 282 CO-Oximeter (Instrumentation Laboratories). Deoxyhemoglobin was taken as the sum of these three subtracted from 100. Oxygen dissociation curves were constructed by equilibrating blood with gas mixtures containing 5% CO_2 , nitrogen, and oxygen. Saturation was measured with the CO-Oximeter, and pH and PO_2 with an IL-1312 blood gas analyzer (Instrumentation Laboratories).

RESULTS

Pseudosickling (Fig 1) was increased by increased osmolality (Table 2) and was greater at 37°C than at 23°C. None was seen after 20 hours incubation at 0°C. There was little difference between tris or phosphate buffers, and there was not much difference if cells were suspended in NaCl or KCl (data not shown). Sickling was enhanced in alkaline buffer, and decreased in acid (Table 2). Although MCHC increased promptly when cells were suspended in hypertonic buffer (within an hour), sickling did not become marked until several hours had passed (Table 2). Consistently, FIK

showed more marked sickling and PEY less; the concentration of Hb Setif within their red cells was highest in FIK and lowest in PEY (Table 1). Very little sickling (which could not be distinguished from crenation) was seen if cells were deoxygenated before incubation.

The sediment collected after overnight ultrafiltration of purified Hb Setif contained long birefringent needle-like crystals (Fig 3). As noted in "Methods," Hb A did not precipitate under the conditions. The sediment after brief ultracentrifugation in Centricon tubes contained tiny clusters of birefringent needles that readily redissolved in buffer.

When dilute (<1 g/dL) solutions of carboxy Hbs A or Setif were centrifuged on Centricon-10 filters, hemoglobin concentration above the filter rose from <1 to 7 to 8 g/dL (Figure 2A). Trace amounts of precipitate formed in samples containing Hb Setif. When the starting solution was more concentrated (Fig 2B), a difference became evident. The hemoglobin concentration of samples containing Hb A rose steadily, exceeding 30 g/dL; considerable amounts of precipitate formed in samples containing Hb Setif at concentrations above 5 g/dL, and the supernatant hemoglobin concentration rose very slowly. It should be emphasized that equilibrium was never achieved in these experiments, and the "solubilities" described below represent differences in the behavior of Hb A and Setif rather than absolute numbers.

Since it seemed likely that a concentration gradient formed above the filter during a 15- to 20-minute "run" (the concentration being highest immediately above the filter), experiments were repeated, stopping the centrifuge every five minutes, mixing the supernatant fluid, and resuming centrifugation. Little difference was seen in comparison with earlier experiments. When precipitates were redissolved and the experiment repeated, results were similar, suggesting that the process observed was reversible precipitation rather than denaturation. Experiments were repeated after dialyzing samples to pH 6.6 or 7.5 (data not shown). There was no difference between the two samples of Hb A (27 g/dL final

Fig 3. Crystals of Hb Setif collected after overnight ultrafiltration of a purified solution through a cellophane membrane.

concentration), but Hb Setif was more soluble at the lower pH (11 v 7 g/dL).

During centrifugation in the presence of Na dithionite under mineral oil, the concentration of "deoxy" Hb Setif continued to rise (final concentration 13.3 g/dL), while the concentration of carboxy Hb Setif rose more slowly (5.2 g/dL final concentration). No difference was seen between samples of deoxy and carboxy Hb A treated in the same fashion: the concentration of both continued to rise, and final concentrations were similar (10.7 v 10.0 g/dL). In a second experiment using more dilute samples, very similar results were obtained (8.4 v 3.9 g/dL for Hb Setif, 7.8 v 6.4 g/dL for Hb A).

A crude hemolysate was prepared, dialyzed against buffered KCl, and concentrated by centrifugation as described above. No precipitate formed up to a concentration of about 10 to 15 g/dL, but small amounts appeared thereafter. Loss of hemoglobin through precipitation (about 40% of the initial amount) was evident when total hemoglobin remaining above the filter was estimated from supernatant volume. To study the behavior of hemolysates in greater detail, artificial mixtures of Hb A and Setif were ultrafiltered. There was little difference between samples containing 10% and 23% Setif (Fig 4). The concentration of samples initially containing 36% rose more slowly, and those containing 50% Hb Setif still more slowly due to loss of hemoglobin that precipitated on the filters as the hemoglobin concentration of the overlying solution increased. The precipitates were composed of both hemoglobins A and Setif (Table 3) but were relatively enriched in the latter compared to the composition of the supernatant mixture. The solubility of Hb Setif in the solutions (which were not in equilibrium with precipitates) was approximately 6 g/dL (total hemoglobin concentration 13.5 to 27.3 g/dL, % Hb Setif 22% to 49%).

Oxygen affinity was measured four to five days after blood was collected. Fresh blood from a normal control (SC) had virtually the same p_{50} at pH 7.4 (28.5 mm Hg) as that stored for four days (27.5, 29.5). FIK had minimally higher affinity than FER (27.5, 27 v 29.0, 28), but there was no suggestion

that FIK's curve diverged from that of the control at high (68%) or low (8%) saturation.

DISCUSSION

Hb Setif, an alpha chain variant, usually comprises 12% to 15% of hemolysates,^{3,12,13} reflecting the usually low proportion of alpha chain variants and perhaps the instability of the abnormal hemoglobin.¹² The high proportion in the blood of FIK (39.5%) reflects the coexistence of one or more thalassemia genes,³ as could be true for higher proportions observed in Saudi Arabian patients.¹¹ The lower proportion in PEY's blood (in comparison to FER) may reflect coexisting iron deficiency.

The most remarkable property of Hb Setif is its capacity to induce sickling of red cells in vitro. "Sickling" has been described in human red cells containing Hb I,¹⁶⁻¹⁸ Barts,¹⁹ and A,¹⁷ in addition to those containing Hb S, and crystals have been described in red cells containing Hb C. The initial patient with Hb I- α thalassemia was a compound heterozygote whose red cells contained 70% Hb I¹⁶; clinically she exhibited no vaso-occlusive manifestations, her fresh red cells were not sickled, and the rheologic properties of her blood were unremarkable. Sickling of Hb Barts has been described only once, and that induced in normal red cells is a laboratory curiosity. Red cells containing crystals of Hb C can be found in freshly collected blood,²⁰ and crystallization can be induced readily if the cells are incubated in 3% NaCl solution.²¹ Vaso-occlusive crises do not occur, but decreased deformability of the red cells has been implicated in the genesis of hemolytic anemia. Hb C is less soluble than Hb A, but the difference is not striking (35 v >46 g/dL²¹).

Red cells of deer,²²⁻²⁴ some sheep,²⁵ some mongooses,²⁶ and other species^{27,28} can be induced to undergo sickling-like changes in vitro. Deoxygenation of the sample is not required; other factors involved include high pH,^{24,29} the presence of EDTA,^{26,27} and in vitro dehydration.²⁶ Only in angora goats are distorted red cells thought to exist in vivo^{28,30} and there polymerized hemoglobin was not found in freshly collected cells. Efforts to produce in deer disability related to the sickling phenomenon have been unsuccessful.^{30,31}

Our experiments with Hb Setif here were carried out with concentrated ("nonideal") solutions. Results are difficult to interpret because a significant portion of the solution is occupied by the solute, and the properties of the solute hemoglobin as a polyelectrolyte may alter its behavior. Equilibrium conditions probably were never achieved, and the "solubilities" recorded are only semiquantitative. With those reservations we interpret our data to show that Hb Setif is much less soluble than hemoglobin A, that mixtures of Hb A and Setif also show decreased solubility, and that conditions that raise the intracellular hemoglobin concentration foster pseudosickling. Of some interest, solubility is lower and (as in deer) sickling is enhanced at pH above 7.4 (Table 2).

The site of amino acid substitution in Hb Setif is an important contact point between α and β chains in the oxy

Fig 4. Centrifugation of artificial mixtures of CO Hb A and Setif in 0.15 mol/L KCl, 0.005 mol/L PO_4 , pH 7.2, over Centricon filters.

Abbreviation: Ppt, precipitate.

conformation. Loss of the contact should reduce oxygen affinity; contrary to expectation, oxygen affinity is only slightly perturbed, but mild instability is produced.¹² The nature of the substitution, tyrosine for aspartic acid, might be expected to produce further anomalies because the side chains of the two amino acids differ in size and polarity.¹³ Aubert et al¹² suggested that the difference produces a change in tertiary structure of the α chain in the vicinity of the substitution and suggested that the normal $\alpha_1\beta_2$ contact within the molecule might be replaced by contacts between α chains in adjacent molecules. Such contacts could explain self-association into crystals, if the sites on the molecules were dissimilar, but it seems more likely that the change in tertiary structure is more widespread than they proposed, and that virtually all portion(s) of the external surfaces of the molecule could be involved.

Our observation that precipitates from mixtures of Hb A and Setif always yielded Hb A on analysis could reflect entrapment of the latter hemoglobin. No attempt was made to wash the precipitates because of erratic results obtained when washing precipitates of pure Hb Setif (see "Methods"). The magnitude of the apparent interaction under certain conditions (70% Hb A, Table 2) suggests that mixed tetramers ($\alpha^A\alpha^{\text{Setif}}\beta_2$) may be important units in crystals within red cells, as they are in polymers forming in mixtures of hemoglobin S with other hemoglobins.⁸⁻¹⁰ Existing as mixed tetramers in the crystal, they would be expected to reassociate into hemoglobins A and Setif during electrophoresis.

Edelstein et al³³ recently suggested that self-association of Hb Setif, when oxygenated, could in turn affect oxygen binding. By analogy to Hb S, which associates in the T (deoxy) conformation and has anomalously low affinity in concentrated solution, one would expect self-association of Hb Setif (in the R or oxy conformation) to increase affinity. As with Hb S, the difference might only be present at high hemoglobin concentration (ie, red cells or artificially prepared solutions of the pure hemoglobin). Raik et al found normal affinity of FIK's blood,³ and we found a minimal difference from normal, but further studies at varying concentrations of the purified abnormal hemoglobin would seem indicated.

At the temperature of the centrifuge (5°C to 10°C) Hb

Setif began to precipitate (crystallize?) from crude hemolysates at Hb Setif concentrations about 6 g/dL and precipitated from solutions containing 25% Hb Setif at a total hemoglobin concentration of 23 g/dL (Fig 4), well below the MCHC of red cells. If blood from the three patients studied is compared at equal sickling (about 20%, Table 2) at 23°C, the intracellular Hb Setif concentration in those cells is similar (5.7, 5.7 and less than 10.2 g/dL, Table 1), despite the difference in temperature.

Pseudosickled cells appear to contain bundles of twisted fibers (Fig 1, and Fig 28 in ref. 4). Those fibers (and earlier stages of molecular aggregation) probably increase red cell rigidity, and one might expect to find infarctions in the hypertonic renal medulla similar to those seen in sickle cell disease or trait. Neither FIK nor FER showed evidence of such infarctions; hematuria and hyposthenuria in their mother was considered by her physician to be a consequence of recurrent infection. Absence of lesions could reflect a difference in solubility due to the difference in temperature between our in vitro studies (5°C to 23°C) and 37°C, but it seems more likely that the lag between red cell shrinkage and sickling (Table 2) may account for absence of clinical findings: erythrocytes probably escape from the vasa recta before significant numbers of polymers or crystals have formed. A similar argument has been used to explain absence of lesions from vascular beds with a very low PO₂ (ie, the myocardium) in sickle cell anemia, but "delay times" in that disease³⁴ are probably much shorter than the lag times seen here.

ACKNOWLEDGMENT

Dr Wilbur Hughes gave us the use of his laboratories at the Institute of Clinical Pathology and Medical Research at Westmead Hospital; we are most grateful to him and his staff for their friendliness and cooperation. We wish to thank Dr M. Hargrave for examining the patients' eyes, Claire Norwood for measuring the proportion of Hb Setif in a large number of samples, the laboratory of Dr Ronald Nagel of the Albert Einstein College of Medicine for scanning electron microscopy, and Dr Gary Ackers for helpful discussion. We are indebted to Dr F. Drupt, who provided us with a copy of his doctoral thesis; the insights it provided were most useful in the present work.

Clinical Experience With Transfusion of Leukocyte-Poor Platelet Concentrates Prepared by Filtration With Prostacyclin

By Hendrik C. van Prooijen, Tineke I. Riemens, and Jan Willem N. Akkerman

Repeated transfusions with platelets from randomly selected donors lead to HLA alloimmunization in about 50% of patients due to lymphocyte contamination of platelet concentrates. Attempts to remove the leukocytes from the platelet concentrates by additional centrifugation steps led to substantial loss of platelets. We report a new procedure for removal of almost all leukocytes with excellent platelet recoveries. Single donor concentrates are treated with 50 ng/mL prostacyclin to inactivate the platelets transiently. The concentrates are then passed through a cellulose-acetate filter to remove the leukocytes. In 30 concentrates this treatment reduced the contamination by leukocytes to

less than 0.1 million per concentrate with a platelet recovery of $89\% \pm 1\%$ (mean $\pm$ SEM). Thirty filtered platelet concentrates transfused to ten thrombocytopenic patients within one hour after filtration were well tolerated and led to corrected count increments of $(22.0 \pm 1.1) \times 10^6$ /mL blood after one hour and normal survival thereafter. In four of five patients these concentrates reduced the bleeding time. We conclude that transient inactivation of platelets by prostacyclin enables optimal removal of leukocytes and may help to reduce alloimmunization during frequent transfusions with platelet concentrates.

© 1987 by Grune & Stratton, Inc.

IN THE LAST few years chemotherapy for patients with acute leukemia has been intensified. This has rapidly increased the need for platelet concentrates as part of the supportive therapy. One of the major problems associated with repeated platelet transfusions is the development of refractoriness, primarily due to HLA alloimmunization.¹⁻³ Only in a minority of the cases are platelet-specific antibodies triggered, which seldom form a problem for platelet transfusions.^{4,5} There is increasing evidence that HLA alloimmunization is induced by the contaminating lymphocytes, and clinical studies have shown that transfusion of leukocyte-poor blood components reduces the incidence of HLA alloimmunization.⁶⁻⁸ At present pooled⁷ or single donor⁸ platelet concentrates are depleted from contaminating leukocytes by additional centrifugation, which reduces the contamination with leukocytes to 0.8 to 2.2×10^8 cells per concentrate. Unfortunately this method leads to a 30% loss of platelets. More leukocytes can be removed by increasing the centrifugation speed, but this treatment further reduces the platelet yield. An alternative method is filtration which has been successfully applied to remove leukocytes from whole blood, but most of the platelets stick to the filters and the loss of platelets is about 80%.⁹

We here report a new procedure to prevent platelet adherence to the filter by inactivating the platelets with prostacyclin. This treatment does not interfere with the removal of leukocytes and results in platelet recoveries of about 90%. Preliminary data show that these platelets recover their hemostatic properties after transfusion.

MATERIALS AND METHODS

Preparation of platelet suspensions for in vitro studies with prostacyclin. The transient inactivation of platelets by prostacyclin was investigated in platelet-rich plasma (PRP) and in single donor platelet concentrates. For the preparation of PRP, venous blood was collected in citrate (0.1 vol of 130 mmol/L sodium citrate) from healthy donors who claimed not to have taken any medication for at least ten days. The blood was centrifuged (120 g, 10 minutes, at room temperature), and the supernatant, PRP, was collected and standardized at 2.5×10^8 platelets/mL by dilution in platelet-poor plasma (PPP).

Single donor platelet concentrates were prepared by cytopheresis with a Haemonetics V50 using ACD-A as anticoagulant. In 30 preparations with a volume of 288 ± 7 mL (mean $\pm$ SEM) the platelet yield was $(4.1 \pm 0.2) \times 10^{11}$ with a contamination of $(3.6 \pm$

$0.5) \times 10^8$ leukocytes. For in vitro studies samples were taken from the concentrates and standardized at 2.5×10^8 platelets/mL by dilution with autologous plasma. The platelet suspensions were treated with different concentrations of prostacyclin, as indicated in the "Results" section. Prostacyclin (PGI₂, Epoprostenol, The Wellcome Foundation Ltd, London) was approved for clinical use. The content of one vial (0.5 mg) was dissolved in 10 mL 0.01 N NaOH, distributed over 20 ampules and stored at -80°C .

Preparation of filtered platelet concentrates. Filtration was performed with cellulose acetate filters (Erypur or Cellselect, Organon Teknika, Amsterdam, The Netherlands). Just before filtration the filters were rinsed with citrate buffer (sodium citrate, 29.9 g/L, anhydrous citric acid, 563 g/L, 2 g/L human albumin, pH 6.5). The prostacyclin solution was thawed and immediately added to the platelet concentrates to obtain a final concentration of 50 ng/mL (0.1 mL of stock solution per 100 mL of platelet concentrate). No adjustments were made for the minor differences in platelet concentration. The concentrates were then passed through the filter at a flow rate of 10 mL/min, and residual platelets in the filter were collected with 200 mL of additional citrate buffer. The recovery after the filtration procedure was measured by counting the leukocytes visually in a Burkert chamber and the platelets in a Baker 810 Trombocounter (Baker, Allentown, PA). The number of leukocytes after filtration was usually extremely low and was therefore measured after concentrating a 20-mL suspension by centrifugation (1000 g, 20 minutes, at room temperature) and resuspension in 0.5 mL of plasma. The filtered concentrates were used for transfusion without prior removal of the prostacyclin.

Aggregation studies. Platelet aggregation was measured in a dual channel aggregometer (Payton Ass, Scarborough, Canada) at a stirring speed of 900 rpm at 37°C following stimulation with 5 μg /mL of collagen (Hormon Chemie, Munchen, FRG).

Transfusion of Filtered Platelet Concentrates. The filtered platelet concentrates were administered to ten patients on a prophylactic basis. Nine patients were treated for acute myeloid leukemia, and one patient was treated for a blast crisis of chronic myeloid leukemia. All patients were profoundly thrombocytopenic (platelet counts $<15 \times 10^6/\text{mL}$) but otherwise clinically stable. Platelet counts were obtained before and one hour after transfusion and every day thereafter. Post-transfusion results were expressed as corrected count increments (CCI) according to the formula:

$$\text{CCI} = \frac{\text{absolute increment} \times \text{body surface area (m}^2\text{)}}{\text{number of transfused platelets} \times 10^{11}}$$

In five patients who showed post-transfusion counts of more than $50 \times 10^6/\text{mL}$ bleeding time measurements were performed by means of the Simplate II method (General Diagnostics, Division of Warner-Lambert, Morris Plains, NJ).

RESULTS

Inhibition of platelet function in vitro by prostacyclin. In an initial series of experiments with PRP the optimal concentration of prostacyclin was sought which induced complete inhibition of platelet function for at least one hour but which also permitted the platelets to recover thereafter. Platelet function was measured as the maximum aggregation in response to collagen and was expressed as a percentage of control (without prostacyclin). Figure 1 illustrates that between 1 and 20 ng/mL prostacyclin completely prevented aggregation. The inhibition was transient, and platelet function rapidly recovered upon addition of 1 ng/mL, whereas much more time was required for spontaneous recovery with higher doses of prostacyclin. Thus a dose of 5 ng/mL of prostacyclin was considered optimal for inhibition of platelet function for at least one hour. Single donor platelet concentrates contained about five times more platelets per volume, and initially the dose of prostacyclin was increased to 25 ng/mL, but we found that twice as much was required for the desired degree of inhibition (Fig 1).

The time required to recover from the prostacyclin inhibi-

Fig 1. Transient inhibition of collagen-induced aggregation by different doses of prostacyclin (ng/mL, final concentrations). Aggregation induced by $5 \mu\text{g/mL}$ of collagen was measured as maximal change in light transmission and expressed as a percentage of a simultaneously run control (no prostacyclin added). The response of PRP (broken lines, 2.5×10^8 cells/mL) was compared with that of platelets collected from single donor concentrates (solid line, containing 50 ng/mL prostacyclin) after dilution in autologous PPP to a final concentration of 2.5×10^8 cells/mL (mean $\pm$ SEM, $n = 6$).

tion could be greatly shortened by centrifugation and resuspension of the platelets in prostacyclin-free medium. In PRP this treatment abolished the effect of up to 20 ng/mL prostacyclin within ten minutes (Fig 2A), whereas in platelet concentrates inactivated with 50 ng/mL prostacyclin the ability to aggregate was restored after 45 minutes (Fig 2B).

Filtration of platelet concentrates. Single donor platelet concentrates were treated with 50 ng/mL prostacyclin within two hours after preparation and were immediately passed through the filter. The number of platelets per concentrate fell from $(4.0 \pm 0.2) \times 10^{11}$ before filtration to $(3.6 \pm 0.2) \times 10^{11}$ thereafter, resulting in a yield of $89\% \pm 1\%$ (mean $\pm$ SEM, $n = 30$). The contamination of leukocytes fell from $(3.6 \pm 0.5) \times 10^8$ before filtration to less than 0.1 million cells per concentrate thereafter, which equals a depletion of more than 99.9%.

Transfusion of filtered platelet concentrates. A total of 30 filtered concentrates was administered at a flow rate of 10 mL/min to ten patients with leukemia. The transfusions were carried out within one hour after filtration when most of the platelets were still inactive. Pulse rate and BP were measured once every ten minutes and remained normal. No other side effects were observed. Table 1 lists the post-transfusion count increments (CCI). Transfusion of filtered

Fig 2. Rapid recovery of aggregability of prostacyclin-inactivated platelets by centrifugation/resuspension in plasma. PRP was treated with different doses of prostacyclin (5 minutes, 22°C) and subsequently pelleted and resuspended in prostacyclin-free, autologous plasma. The recovery of collagen ($5 \mu\text{g/mL}$)-induced aggregation was expressed as a percentage of control (Fig 2A, solid lines) and compared with the spontaneous recovery without prostacyclin removal (Fig 2A, broken lines). Figure 2B illustrates similar experiments using platelets obtained from single donor concentrates (mean $\pm$ SEM, $n = 4$).

Table 1. Post-transfusion Platelet Counts

Time After Transfusion	Increment ($\times 10^6/\text{mL}$)	
	Absolute	Corrected
1 h	40.1 $\pm$ 2.5	22.0 $\pm$ 1.1
18-24 h	28.5 $\pm$ 2.0	14.8 $\pm$ 0.8
42-48 h	13.0 $\pm$ 1.3	7.2 $\pm$ 0.7

NOTE. Mean $\pm$ SEM; n = 30.

concentrates resulted in CCIs of 22.0 and 14.8 $\times 10^6/\text{mL}$ blood at one hour and between 18 and 24 hours after transfusion respectively. For comparison, 26 transfusions of single donor HLA-matched platelets, administered to a comparable group of patients, produced a mean corrected count increment at one hour of 22.1 $\pm$ 2.8 $\times 10^6/\text{mL}$ and a mean corrected count increment at 24 hours of 10.7 $\pm$ 1.2 $\times 10^6/\text{mL}$. Five patients were transfused with filtered platelet concentrates during the thrombocytopenic phase of their remission induction therapy, and none of the patients showed signs of hemorrhage. Bleeding times were performed in these five patients when post-transfusion counts were more than 50 $\times 10^6$ platelets/mL blood. In four patients a significant reduction of the bleeding time was observed (Table 2).

DISCUSSION

For many years blood filters have been used to remove leukocytes from whole blood. The best results were obtained with cellulose-acetate filters and cotton-wool filters, both leading to a leukocyte depletion of about 98%.⁹ Unfortunately these filters also removed most of the platelets and were therefore unsuitable for removing leukocytes from platelet concentrates. The present study shows that the loss of platelets during filtration can be reduced to a minimum by transiently inactivating these cells with prostacyclin. Currently platelet concentrates are best depleted from leukocytes by additional centrifugation. Such a procedure takes about 15 minutes per concentrate and is therefore faster than our filtration technique, which takes about twice as long. The great advantage of our filtration procedure lies in the much better platelet recovery and the almost complete removal of leukocytes, resulting in concentrates that may be optimally effective for preventing HLA alloimmunization after repeated platelet transfusions. One may expect that these concentrates will rescue the need for HLA-matched platelets, which will make up for the cost of the filters and will

even be more economical. Although the prostacyclin treatment appears successful in *in vitro* studies, two questions must be addressed before the method can be applied clinically: (1) How safe is the use of prostacyclin, which is known in certain conditions to induce hypotension? and (2) Are the transfused platelets hemostatically effective? Prostacyclin has been successfully applied in patients with peripheral vascular disease,¹⁰ chronic renal disease,¹¹ and thrombotic thrombocytopenic purpura.¹² In a recent study in normal volunteers, clinical tolerance, inhibition of platelet aggregation, and intracellular levels of cyclic AMP were compared during infusions of prostacyclin at rates up to 15 ng/kg/min.¹³ For short-term infusions (up to 60 minutes) the maximum tolerated rate was 10 ng/kg/min. The increase of cyclic adenosine monophosphate levels and inhibition of the circulating platelets were transient and returned to pretreatment values within 30 minutes after the end of infusion. In our study filtered platelet concentrates were transfused at a rate of 10 mL/min. Assuming that all prostacyclin added to the platelets prior to filtration was still effective at the time of transfusion, this would equal an infusion rate of about 6 ng/kg/min, which is well below the maximum tolerated rate. Indeed, no signs of hypotension or other side effects were observed. The second question is more difficult to answer. Our *in vitro* studies show that the prostacyclin-treated platelets regained the ability to aggregate in response to collagen after a few hours incubation at room temperature. This recovery period could be greatly shortened by pelleting the cells and resuspending them in prostacyclin-free medium. Although this provides a means to reactivate the platelets prior to infusion, we chose to transfuse the inactive platelets. Apart from bypassing a time-consuming washing step, this procedure protected the platelets optimally against *in vitro* activation and enabled them to recover in the blood stream. Probably the dilution *in vivo* in the circulating blood mimics the situation *in vitro* when the cells are resuspended in fresh plasma, enabling the platelets to become hemostatically active. Our *in vivo* data appear to support this concept and show a reduction in bleeding time in four of five patients following transfusion of prostacyclin-treated platelets. Obviously the question of whether transient inactivation *in vitro* improves the hemostatic functions *in vivo* requires a more detailed study.

The ultimate goal for the preparation of leukocyte-depleted platelet concentrates is to prevent HLA alloimmunization in patients who are frequently transfused with platelets. Recent studies by Murphy et al⁸ have already revealed a reduction from 48% to 16% in alloimmunization when the leukocyte contamination was kept below about 2×10^8 per concentrate. With our technique the contamination is less than 1×10^5 leukocytes per concentrate, and a further reduction in alloimmunization may be expected. Thus the use of prostacyclin-treated, filtered platelet concentrates may reduce the incidence of the troublesome febrile transfusion episodes that are inherent to current transfusion regimes, prolong the time when random donor concentrates are effective, and reduce the need for HLA-matched donor platelets.

Table 2. Simplex Bleeding Times Before and After Transfusion of Filtered Platelet Concentrates

Patient	Platelet Count ($\times 10^9/\text{mL}$)		Bleeding Time		
	Before	After	Before	After I	After II

Hypodiploidy Is Associated With a Poor Prognosis in Childhood Acute Lymphoblastic Leukemia

By Ching-Hon Pui, Dorothy L. Williams, Susana C. Raimondi, Gaston K. Rivera, A. Thomas Look, Richard K. Dodge, Stephen L. George, Frederick G. Behm, William M. Crist, and Sharon B. Murphy

Leukemic cells from 31 (7.6%) of 409 children with newly diagnosed acute lymphoblastic leukemia (ALL) had a hypodiploid karyotype. The patients' ages ranged from 0.8 to 17 years (median, 5 years) and their initial leukocyte counts from 1.0 to $132 \times 10^9/L$ (median, $12.7 \times 10^9/L$). Modal chromosome numbers for the leukemic stem lines were 45 in 26 cases, 28 in two cases, and 26, 36 and 43 in one case each. Seven cases had one to three additional abnormal lines due to clonal evolution. Chromosome 20 was lost most frequently (nine cases). Structural abnormalities—including chromosomal translocations (21 cases), deletions (ten cases), duplications (two cases), or inversions (one case)—were common findings; the nonrandom translocations consisted of the $t(1;19)(q23;p13.3)$ in

two pre-B cases and $tdic(9;12)(p171;p172)$ in three cases of common ALL. When compared with hyperdiploid cases (>50 chromosomes), ALL with hypodiploidy was found to have a poorer outcome and was more likely to be associated with chromosomal translocations, higher serum lactic dehydrogenase levels, and age <2 or ≥ 10 years. Moreover, patients with hypodiploid ALL fared as poorly as those with pseudodiploid karyotypes, even though their leukocyte counts and serum lactic dehydrogenase levels were lower and they had a comparable frequency of leukemic cell translocations. Hypodiploidy is therefore an unfavorable karyotypic feature in childhood ALL.

© 1987 by Grune & Stratton, Inc.

CHROMOSOMAL abnormalities have attracted much recent attention as independent prognostic factors in childhood acute lymphoblastic leukemia (ALL). The first clinically relevant subgroup to be described had hyperdiploid stem lines with >50 chromosomes per leukemic cell and comprised about 30% of children with ALL, a subset that has proved to have the most favorable prognosis.¹⁻⁴ Subsequent studies have shown that the pseudodiploid karyotype, defined by 46 chromosomes with structural alterations, is associated with the poorest response to therapy.²⁻⁷ Hypodiploidy, by contrast, is a relatively uncommon finding, affecting only 3% to 9% of patients with ALL,²⁻⁸ and its prognostic significance has been controversial. Some investigators suggest that hypodiploidy at diagnosis is a favorable risk feature,^{1,5,7} while others have shown it to be associated with a poor treatment outcome.^{4,8} In this study, which includes the largest number of banded cases of ALL reported to date, we demonstrate that leukemic cell hypodiploidy is associated with a poor prognosis.

MATERIALS AND METHODS

Of 710 consecutive children with newly diagnosed ALL who were admitted to St. Jude Children's Research Hospital from November 1978 to October 1986, 421 had complete G-banding of all chromosomes from bone marrow leukemic cells. Twelve of these patients had B cell ALL and were treated separately. The present study was restricted to the 409 patients with non-B ALL who had completely banded leukemic cell chromosomes to avoid possible underrepresentation of clonal abnormalities. These children were enrolled in three Total Therapy studies⁹⁻¹¹ after informed, written consent was obtained. The investigations were approved by the institution's clinical trials review committee.

Cytogenetic analysis. Bone marrow samples were processed according to the method of Williams et al.¹² Marrow cells were collected in RPMI 1640 medium containing 30% fetal calf serum with added L-glutamine and antibiotics. They were immediately exposed to colcemid (final concentration, $0.06 \mu g/mL$), rinsed twice in Hanks' balanced salt solution (HBSS), and exposed to hypotonic KCl (0.075 mol/L) for a total of 32 minutes at room temperature, including periods of mixing, standing, and centrifugation. They were then fixed twice in 3:1 methanol-acetic acid (vol/vol) for 15 minutes and ten minutes, after which slides were prepared by a flaming technique and natural aging for 0 to 7 days. Metaphase preparations

were G-banded by a modification of the trypsin method of Seabright.¹³

Chromosomal abnormalities were classified according to the International System of Human Cytogenetic Nomenclature (1985).¹⁴ The definition of an abnormal stem line was that proposed by the Second International Workshop on Chromosomes in Leukemia.¹⁵ A case was considered abnormal if it had an abnormal clone, regardless of the proportion of normal metaphases. For cases with more than one leukemic line due to clonal evolution, only the primary line was included in the analyses, with the exception of a single case of hypodiploidy in which the secondary line containing a translocation was used.

DNA content determination by flow cytometry. Leukemic marrow samples were stained with a DNA-specific dye, propidium iodide, and were analyzed by flow cytometry as previously described.¹⁶ The DNA index (ratio of DNA content in leukemic G_0/G_1 cells v normal diploid G_0/G_1 cells) was determined. This measure correlates closely with chromosome number (ploidy); hence leukemic cells with a normal chromosome number have a DNA index of 1.0.

Blast cell phenotyping. The diagnosis of ALL was based on morphological criteria of the French-American-British (FAB) group¹⁷ and negative myeloid-associated cytochemical findings. Cell-surface antigens were detected by a standard indirect immunofluorescence assay with monoclonal antibodies (MoAbs) to lym-

phoid-associated antigens, including J5 (common ALL antigen, CALLA, CD-10), T11 (CD-2), T101 (CD-5), and T-3 (CD-3). Blast cells were also tested for surface and cytoplasmic immunoglobulin and rosette formation with sheep erythrocytes. Depending on the pattern of reactivity, the cells were classified as T, B, pre-B, CALLA⁺ early pre-B (common), or CALLA⁻ early pre-B (so-called undifferentiated), as previously described.¹⁸

Statistical analysis. Differences in the distribution of clinical and biological features among cases with hypodiploidy v other karyotypic subtypes were tested by the two-tailed Fisher exact test or the Pearson chi-square test. The Mann-Whitney test was used to examine the differences in the medians for continuous variables. To account for the problem of multiple significance testing,¹⁹ adjustment was made to the target significance level (0.05) by simply dividing it by the number of multiple tests.⁴ Hence a *P* value of at most 0.012 was required to declare statistical significance in those instances; the nominal *P* values are reported in Table 1.

Time-to-failure curves were constructed by the Kaplan-Meier procedure,²⁰ and differences were analyzed by the Cox-Mantel test,²¹ with adjustment for multiple comparisons.²² Time to failure was defined as the interval between achievement of remission and relapse or death due to any cause. Patients who did not enter complete remission were considered as failures and assigned a failure time of zero. A stratified log-rank test²³ was used to analyze differences in time to failure between the hypodiploid and hyperdiploid groups, after adjusting for age, translocation, leukocyte count, and serum lactic dehydrogenase level. The Cox proportional hazards model²⁴ was also used to determine if hypodiploidy added prognostic information beyond that of the above factors.

RESULTS

Thirty-one (7.6%) of the 409 patients had leukemic cell hypodiploidy (Table 2). These 14 boys and 17 girls ranged in age from 9 months to 17 years (median, 5 years). Of the 30 cases tested for blast cell immunophenotype, 17 had common ALL, 8 pre-B, and 3 T cell; the remaining two cases had blasts that expressed CALLA but were not tested for cytoplasmic immunoglobulin. The morphological subtypes of blast cells were FAB L1 in 26 patients and L2 in 5. Leukocyte counts ranged from 1.0 to $132 \times 10^9/L$ (median, $12.7 \times 10^9/L$), platelet counts from 3 to $483 \times 10^9/L$ (median, $53 \times 10^9/L$), and hemoglobin levels from 2.9 to 14.6 g/dL (median, 8.3 g/dL). Nine patients had massive

hepatosplenomegaly with a liver or spleen edge palpable more than 5 cm below the costal margins. Patients 2, 3, and 15 had initial CNS leukemia, and patient 24 had a mediastinal mass at diagnosis.

The modal chromosome numbers of the primary leukemic cell lines were 45 in 26 cases, 28 in two cases, and 26, 36, and 43 in one case each. Two or more leukemic lines derived from clonal evolution were found in seven patients (Nos. 3, 10, 11, 13, 16, 23, and 24). All but one case with near haploidy (26 chromosomes) had their blast cell G_0/G_1 DNA content determined by flow cytometry. Except for cases 10 and 23, each with 28 chromosomes (near haploidy), and case 22 with 36 chromosomes, the remaining 27 cases with 43 to 45 chromosomes had cellular DNA content values indistinguishable from normal diploid (DNA index = 1.0).

Hypodiploidy resulted from whole chromosome losses in 20 patients, from loss of a fragment of a chromosome involved in the translocation in 7, and from dicentric chromosome in 4. None of the cases showed a gain of whole chromosomes (Fig 1). Chromosome 20 was lost most frequently, and in three cases of common ALL a missing chromosome 20 was the only abnormality. Notably, none of the cases showed a loss of chromosome 21. Structural abnormalities included translocations in 21 cases (68%), deletions in 10 (32%), duplications in two, and an inversion in one. The structural abnormalities most frequently involved the short arms of chromosomes 9 and 12. Two nonrandom translocations were identified: t(1;19)(q23;p13.3) in two pre-B cases and t(9;12)(p11;p12) in three of common ALL. Deletions of chromosome 6 between q21 to q25 were found in four cases.

Table 1 shows the presenting features of patients according to chromosome ploidy. Hypodiploid cases had significantly lower leukocyte counts ($P = 0.001$) and lower serum lactic dehydrogenase levels ($P = 0.003$) than did those with a pseudodiploid karyotype but had a similar frequency of translocations. Hypodiploidy was associated with a higher frequency of leukemic cell chromosomal translocations ($P < 0.001$), higher serum lactic dehydrogenase levels ($P = 0.002$), and a greater proportion of patients with ages <2 or ≥ 10 years ($P = 0.015$) than was hyperdiploidy defined

*Values for primary and secondary leukemic lines.

+Contained three other similar leukemic lines, one with an additional translocation, from clonal evolution.

Fig 1. Structural and numerical chromosomal abnormalities in hypodiploid cases. (A) The closed blocks represent specific chromosomes involved in translocations; open blocks represent all other abnormalities not associated with translocations. Each breakpoint is depicted once. The structural abnormalities most frequently involved the 9p and 12p arms. (B) The open blocks represent chromosomal losses in cases of near haploidy; closed blocks represent losses in other hypodiploid cases. The loss of chromosomes most frequently involved number 20 and did not involve number 21.

by >50 chromosomes. The frequency of translocations was also significantly higher in hypodiploid cases compared to those with 47 to 50 chromosomes ($P = 0.001$). There were no significant differences between the hypodiploid group and others in sex ratio, race distribution, frequency of CNS leukemia or mediastinal mass, liver or spleen size, hemoglobin level, platelet count, and distribution of FAB morphological subtypes and immunophenotypes (data not shown).

Forty-two cases in this study, half with a T cell phenotype, had only normal chromosomes on marrow karyotype analyses. As expected, comparison of this ploidy group with hypodiploid cases disclosed significant differences in frequency of translocations and immunophenotypes; however, with improved cytogenetic techniques the finding of "normal" diploid karyotypes is becoming increasingly rare in our laboratory.²⁵ Hence the normal karyotypes most likely reflect normal residual marrow elements in cases in which the leukemic metaphase cannot be easily studied (eg, T cell ALL).

Since the distribution of ploidy groups was similar in the three successive clinical trials, patients were combined for analysis of time to failure. Patients with hypodiploid karyotypes were more likely to fail therapy than were those with >50 chromosomes ($P = 0.007$, Fig 2). There was no significant difference in outcome between the hypodiploid and the other ploidy groups.

Using the stratified log-rank test, we could find no difference in time to failure between the hypodiploid cases and hyperdiploid >50 group after adjustment for the selected

Fig 2. Kaplan-Meier estimates of time-to-failure rates. Patients with leukemic cell hypodiploidy fared significantly worse than those with chromosomes >50 ($P = 0.007$). There was no significant difference in the failure rates between hypodiploid cases and those with pseudodiploidy ($P = 0.99$) or those with other ploidy, defined as 47 to 50 chromosomes or normal karyotype ($P = 0.33$). Numbers along the curves represent patients at risk of failure at various times.

important prognostic factors ($P = 0.43$). Cox regression analysis showed that hypodiploidy added only marginal prognostic information beyond that conferred by leukocyte count, age, serum lactic dehydrogenase level, and chromosomal translocation ($P = 0.08$).

DISCUSSION

In this large series of pediatric ALL cases with completely banded karyotypes, we have shown that hypodiploidy occurs infrequently (7.6% of cases) but is clearly associated with an adverse treatment outcome. In contrast to cases with >50 chromosomes, hypodiploid cases were more likely to have ages <2 or ≥ 10 years, higher serum lactic dehydrogenase levels, and leukemic cell chromosomal translocations. Age has consistently been an independent predictor of treatment outcome in childhood ALL, with patients <2 years or ≥ 10 years faring much worse than children in the intermediate age group.²⁶ Recently, we reported that increased serum lactic dehydrogenase levels confer a poor prognosis and may provide a more reliable estimate of the total body burden of leukemic cells than does leukocyte count alone.²⁷ There is now compelling evidence that leukemic cell chromosomal translocations are the karyotypic abnormality with the most profound impact on treatment outcome.^{4,8,28} In our experience patients with any chromosomal translocation have a sixfold greater risk of early treatment failure than do those without such abnormalities.²⁸ Thus the poor treatment responsiveness of hypodiploid ALL can be attributed, at least in part, to its associated high-risk clinical and biological features. The small number of hypodiploid cases precluded further subset analyses of risk features among this group.

We think it noteworthy that patients in the hypodiploid and pseudodiploid groups showed equally poor responses, despite lower leukocyte counts, lower serum lactic dehydrogenase levels, and a lack of cytogenetic abnormalities with known adverse influence, such as $t(4;11)$, $t(8;14)$, and $t(9;22)$ in the former group. Since ages and frequencies of chromosomal translocations were similar in these subsets of

patients, one could postulate additional factors underlying the poor outcome in hypodiploid cases. In this respect it is tempting to speculate on the significance of chromosome loss in relation to the concept of "anti-oncogenes"^{29,30} or recessive mutations in somatic cells,^{31,32} as proposed for certain childhood malignancies. This theory holds that dysfunction or loss of anti-oncogenes may be important in tumorigenesis, by allowing abnormal expression of proto-oncogenes or the loss of differentiation products that are encoded by anti-oncogenes.^{29,30} Alternatively, the malignancy may arise as a consequence of recessive mutations in somatic cells that are unmasked by genetic events that resulted in the loss of the unaffected gene in the homologous chromosome.^{31,32} In any event, hypodiploid cells may be more likely than other cells to lose their suppressor genes or to express recessive oncogenes, possibly leading to more aggressive disease.

Near-haploid ALL is rare. The reported cases are associated with 26 to 28 chromosomes in leukemic cells that retain at least one homolog of each chromosome, some being disomic. This type of leukemia may have a second line containing twice the near-haploid number, as seen in two of the three cases in this study. This doubling of chromosome number is a form of clonal evolution. In general these patients have a very poor outcome.³³ Two of the three patients in this study with near haploidy have failed.

Two types of nonrandom translocations were observed: the $t(1;19)(q23;p13.3)$ in two cases of pre-B ALL^{18,34,35} and the $tdic(9;12)(p1?1;p1?2)$ in three cases of common ALL. The $tdic(9;12)$ has recently been described in association with ALL of B cell precursors, hypodiploidy, and male predilection.³⁶ It may be important that the *c-Kirsten-ras* 2 proto-oncogene is located at 12p12,³⁷ the region involved in this translocation.

The finding of multiple leukemic lines at diagnosis is not unusual in ALL. Kaneko et al³⁸ reported this result in about one fifth of 50 consecutive cases of ALL (31 in children and 19 in adults). At our center 26% of 116 consecutive cases had multiple lines at the time of diagnosis.³⁹ In most of them the multiple lines were the result of clonal evolution; only rarely did they appear to represent two independent stem lines (ie, biclonal).³⁹ All seven cases of multiple stem lines that we observed had evidence of clonal evolution. The clinical significance of ALL defined by two or more leukemic lines remains unknown.

Studies comparing cellular DNA content measurements by flow cytometry with cytogenetic determinations of leukemic cell ploidy have disclosed an excellent correlation for both adults and children.^{40,41} The advantages of flow cytometry are not simply that the measurements are relatively easy and rapid to perform, but also that a high degree of statistical accuracy is obtained through analysis of large numbers of cells independent of low proliferative rate and mitotic index. However, this method cannot distinguish pseudodiploid cells with translocations or other abnormalities from normal cells and does not reveal the identity of individual chromosomes gained or lost. Moreover, it is not sensitive enough to detect a small gain or loss of total chromosomal DNA. All of the 27 cases with 43 to 45 chromosomes that were tested in this study had a DNA index value of 1.0 (see Table 2) and hence

could not be identified as hypodiploid with use of this technique.

Recently, cytogenetic techniques have improved to the degree that virtually all cases of childhood ALL can be shown to have clonal chromosome abnormalities.²⁵ While the distinction between hypodiploid 43-45 and pseudodiploid ALL cases may not be critical for treatment planning, as both groups have poor outcomes, cytogenetic analysis identifies the subgroup with translocations and therefore a worse

prognosis and could contribute to the understanding of leukemogenesis by discovery of nonrandom changes. The basis for the nonrandom nature of chromosomal loss in childhood ALL and the associated poor treatment outcome remains to be elucidated.

Effects of B Cell Stimulatory Factor-1/Interleukin 4 on Hematopoietic Progenitor Cells

By Christian Peschel, William E. Paul, Junichi Ohara, and Ira Green

B cell stimulatory factor-1 (BSF-1)/Interleukin 4 (IL 4) is a T cell product originally characterized on the basis of its actions on B lymphocytes. Recently it has been reported that BSF-1 activates T cell and mast cell lines. We now provide evidence that BSF-1, purified to homogeneity, also has a broad spectrum of activity on hematopoietic progenitor cells (HPC). However, like its action on B cells, proliferative effects were only observed when BSF-1 was combined with an additional factor. Thus BSF-1, in costimulation with recombinant G-CSF, enhances the proliferation of granulocyte-macrophage progenitor cells (CFU-GM). BSF-1 increases the proliferation of CFU-e in the presence of recombinant erythropoietin (rEPO). Furthermore, BSF-1 induces, together with rEPO, colony formation by primitive

erythroid (BFU-e) and multipotent (CFU-mix) progenitor cells comparable to that observed with rEPO and interleukin 3 (IL 3). BSF-1 is also active as a megakaryocyte colony-stimulating factor; in combination with recombinant interleukin 1, rEPO or the supernatant of the T cell hybridoma FS7-20.6.18, BSF-1 induces megakaryocyte colony formation (CFU-Mk). The same factors that synergize with BSF-1 also enhance CFU-Mk proliferation induced by IL 3. Although the precise mechanisms of action of BSF-1 on HPC is not yet known, we propose that BSF-1 represents an activation factor for HPC and prepares the progenitor cells to respond to specific growth or differentiation factors.

© 1987 by Grune & Stratton, Inc.

B CELL stimulatory factor-1 (BSF-1)/interleukin 4 is an ~20,000 mol wt T cell product that was originally described as a costimulant with anti-IgM antibodies for the entry of resting B cells into the S phase of the cell cycle.¹⁻³ It is now known that BSF-1 increases the expression of class II MHC molecules on resting B cells,^{4,5} promotes secretion by B lymphocytes of IgG₁ and IgE,^{6,7} and induces proliferation of colony-forming B cells (C. Peschel, manuscript in preparation). In addition to these multiple actions on B lymphocytes, BSF-1 has recently been shown to promote the growth of helper T cell lines and to be identical with a factor that enhances the growth of mast cell lines in response to interleukin 3 (IL 3).⁸⁻¹¹ In this study we now demonstrate that BSF-1 has activities on several hematopoietic progenitor cell types.

The proliferation and differentiation of hematopoietic progenitor cells (HPC) in vitro is regulated by a family of specific growth factors, usually referred to as colony stimulating factors (CSFs).¹² Interleukin 3 (IL 3), also designated as multi-CSF, promotes the in vitro proliferation of murine pluripotent hemopoietic stem cells, primitive erythroid (BFU-e), megakaryocytic (CFU-Mk), and granulocyte-macrophage (CFU-GM) progenitor cells and mast cells.¹³⁻¹⁶ The effects of other growth factors are mainly restricted to one cell lineage. A group of CSFs regulates the growth of CFU-GM. G-CSF and M-CSF preferentially stimulate the proliferation of granulocytes and macrophages respectively,

whereas GM-CSF stimulates the production of both granulocytic and macrophage cells.^{17,18} In recent experiments it became evident that recombinant GM-CSF has a broader spectrum of activity and provides stimulating activity for erythroid and multipotent progenitor cells^{19,20} and megakaryocytic progenitor cells.¹⁶ Erythropoietin (EPO) has similar properties as a growth factor for mature erythroid progenitor cells (CFU-e)²¹ and in combination with an additional activity²² mainly provided by IL 3¹⁵ for BFU-e. The effect of erythropoietin on CFU-e and BFU-e can also be enhanced by another factor designated as erythroid potentiating activity (EPA).^{23,24} The in vitro proliferation of murine CFU-Mk has been proposed to be regulated by two factors.²⁵ CSF-Mk is identical with IL 3²⁶; a megakaryocyte potentiating activity (MkPA) that enhances the growth of megakaryocyte colonies in the presence of IL 3 has been reported to be present in several crude cell supernatants.^{16,26,27}

The proliferative activity of the CSFs is restricted to hematopoietic cells, with the exception that IL 3 also has an effect on the differentiation of immature T cells²⁸ and stimulates the proliferation of B cell precursors.²⁹ By contrast, BSF-1, which has major actions on mature B and T cells, is shown here to have significant action on hematopoietic progenitor cells. In costimulation with different growth factors, BSF-1 induces in vitro proliferation of multipotent (CFU-mix) and restricted myeloid (CFU-GM), erythroid (BFU-e, CFU-e), and megakaryocyte (CFU-Mk) progenitor cells.

MATERIALS AND METHODS

Animals. Female Balb/c mice, 6 to 10 weeks of age, were obtained from the breeding facilities of the National Institutes of Health, Bethesda, MD, and utilized throughout these studies.

Cell separation. Bone marrow cells were obtained from femurs and tibiae, and single cell suspensions were prepared in McCoy's 5A medium (Flow Laboratories, McLean, VA) containing 5% fetal calf serum (FCS; Hyclone, Logan, UT), by passage through a thin needle. The McCoy's 5A medium was supplemented with 1 mmol/L sodium pyruvate, MEM Vitamins (1:100), MEM nonessential (1:100), and essential (1:50) amino acids, 2 mmol/L L-glutamine, 16 µg/mL L-asparagine, 10 µg/mL L-serine, 10 mmol/L HEPES buffer, penicillin-streptomycin, and 5×10^{-5} mmol/L 2-mercapto-

ethanol, and adjusted to pH of 7.2. After enrichment of the mononuclear cell fraction (MNC) by centrifugation over Ficoll-Hypaque (FH, density 1.077g/mL, Pharmacia, Piscataway, NJ), interface cells were depleted of adherent cells by two consecutive adherence procedures in tissue culture dishes (100-mm diameter, Falcon, MA) at a cell density of 1×10^6 MNC/mL. Nonadherent cells obtained after the second incubation period of 90 minutes were incubated with a cocktail of appropriate dilutions of Thy1.2, Lyt-1, and Lyt-2 antibodies to remove T cells (Beckton Dickinson, Sunnyvale, CA) for 30 minutes on ice; after centrifugation cells were suspended in a 1:10 solution of low-tox-M rabbit complement (Accurate Chemical, Westbury, NY) with a monoclonal mouse antirat κ chain antibody (MAR 18.5) and incubated for 45 minutes at 37°C. This adherent cell and T cell-depleted bone marrow cell population was used in all experiments. In certain experiments a monoclonal antibody (MoAb) produced by the hybridoma cell line RA33A16.1 (obtained from American Type Culture Collection, Rockville, MD), which recognizes the B220 antigen, was additionally used with complement to remove B and pre-B cells.³⁰

Growth factors. BSF-1 was purified from supernatant fluids of 4 β -phorbol-12 β -myristate-12 α -acetate (PMA) activated EL-4 cells by a combination of affinity chromatography and high-performance liquid chromatography (HPLC). Briefly, 4L of EL-4 Sn was passed over an affinity column of 10 mL Sepharose-4B conjugated with 20 mg γ -globulin from a monoclonal anti-BSF-1 (11B11) ascites³¹ at a flow rate of 4 mL/min. After washing the column thoroughly with 2 L glass-distilled water, BSF-1 was eluted with 0.1% trifluoroacetic acid (TFA). The eluate was loaded onto a C18-reversed phased HPLC column (Supelco, Inc, Bellefonte, PA) with a Perkin-Elmer HPLC system (Perkin-Elmer Corp, Norwalk, CT) as described previously.³² The column was developed with a linear gradient of 35% to 55% acetonitrile in 0.1% TFA over 60 minutes at a flow rate of 0.5 mL/min. The detailed procedure will be described elsewhere (J. Ohara et al, manuscript in preparation). The resultant BSF-1 migrated as a single molecular species of mol wt 20,000 on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The N-terminal amino acid sequence of this material is identical to that inferred from the nucleotide sequences of cDNA clones of BSF-1.^{33,34} A U/mL of BSF-1 is the concentration required for half maximal stimulation of ³H-thymidine uptake by purified splenic B cells (10^5 cells/mL) stimulated with goat antimouse IgM antibody (5 to 10 μ g/mL).³²

Highly purified IL 3 was kindly provided by J. N. Ihle, Frederick, MD.³⁵ Recombinant human erythropoietin (rEPO) purified by sequential chromatography was purchased from Amgen (Thousand Oaks, CA). Recombinant human interleukin 1 α (IL 1) was generously provided by Hoffman LaRoche (Nutley, NJ), and recombinant human G-CSF was kindly provided by Amgen.³⁶ The supernatant of the T cell hybridoma FS7-20.6.18 that has recently been described to contain megakaryocyte potentiating activity²⁷ was kindly supplied by P. Marrack (National Jewish Hospital, Denver, CO).

Hematopoietic progenitor assays. Colony-forming assays were performed in a modified agar culture system as previously described.³⁷⁻³⁹ Nonadherent T cell-depleted bone marrow cells were suspended in culture medium containing 10% heat-inactivated FCS and 0.3% Bacto-Agar held at 37°C (Difco, Detroit). Aliquots of 0.25 mL of this mixture containing 2×10^4 or 4×10^4 viable cells were pipetted into Nunclon 4-well multidishes (Nunc, Denmark). After solidification at room temperature, a liquid overlayer of 0.25 mL culture medium containing 10% fetal calf serum (FCS) and the growth factors to be studied was added. The growth factors tested in the different progenitor cell assays are shown in Table 1. All stimulating factors suspended in the liquid overlayer were applied in double concentration to achieve final dilutions in the whole culture

system as described in Table 1 and Results. After incubation in 6% CO₂ in fully humidified atmosphere for 2.5 to seven days, the whole agar cultures were fixed with 2.5% glutaraldehyde, washed in distilled water for four hours, mounted on microscopic slides, and dried on a slide warmer. May-Grünwald-Giemsa,³⁷ benzidine,⁴⁰ and acetylcholinesterase⁴¹ stainings were performed on the dried agar sheets as described; the slides were permanently mounted with Permount (Fisher, Fairlawn, NJ); and numbers of colonies or clusters were scored under a light microscope.

A summary of the progenitor cell assays, definition of colony types, and factors used, as detailed below, are also given in Table 1.

CFU-GM assay. 2×10^4 cells/well were incubated with G-CSF 10 to 200 U/mL alone or in combination with BSF-1 30 U/mL or IL 1 5 U/mL or IL 3 50 U/mL for six to seven days. Granulocytic clusters (10 to 50 cells) and colonies (>50 cells) were distinguished in cultures stimulated with G-CSF $\pm$ BSF-1. In IL 3-containing cultures only colonies were counted.

CFU-e assay. 2×10^4 cells/well were stimulated with rEPO 0.1 U/mL or 1.0 U/mL $\pm$ BSF-1 30 U/mL or BSF-1 30 U/mL alone. The CFU-e number was evaluated at 2.5 to three days of incubation in preparations stained for benzidine to identify hemoglobin-containing cells. CFU-e were defined as clusters of more than eight normoblast-like hemoglobinized cells. Such clusters do not contain more than 20 normoblasts.

BFU-e and CFU-Mix assay. For assays of erythroid (BFU-e) and mixed erythroid (CFU-mix) progenitor cells, 4×10^4 cells/well were incubated with rEPO 2.0 U/mL in combination with IL 3 50 U/mL or BSF-1 30 U/mL for seven days and stained with benzidine. Such colonies generally contain more than 50 cells. Control cultures containing medium alone, IL 3, or BSF-1 alone were always included. The composition of mixed erythroid colonies was also evaluated in preparations stained for acetylcholinesterase to identify megakaryocytes. In these preparations erythroid cells were identified by their typical morphology. Mixed erythroid colonies that contained erythroid cells and megakaryocytes and/or granulocytes were distinguished from pure erythroid colonies.

CFU-Mk assay. 4×10^4 cells/well were stimulated with BSF-1 30 U/mL, IL 3 1 to 100 U/mL alone or in combination with IL 1 5 U/mL, rEPO 2.0 U/mL or FS7-20.6.18-conditioned medium (CM) 5% as source of MkPA. Colonies were defined as aggregates of more than three large acetylcholinesterase-positive cells⁴¹ after seven to eight days of incubation. In cultures stimulated with EPO and IL 3 or BSF-1, mixed colonies containing megakaryocytes, erythroid cells, and/or granulocytic/monocytic cells were distinguished from pure megakaryocytic colonies.

Use of anti-BSF-1 antibody. In all hematopoietic progenitor cell assays described above, the specificity of the biological activity induced by added BSF-1 was confirmed by the addition of a monoclonal rat anti-BSF-1 antibody, designated as 11B11³¹ to the cultures. The anti-BSF-1 antibody was used in dilutions of 1:500 of ascitic fluid in selected cultures and was added to the cultures together with BSF-1 or other growth factors during the whole incubation period.

Statistical analysis. All cultures on a single day were performed at least in duplicate, and colony counts of parallel cultures were pooled. The same experiments were repeated three to four times over a period of time, and the results were expressed as mean values of these different experiments. The differences between corresponding experiments have been examined by the two-tailed Dunnet test.

RESULTS

The purpose of this study was to determine the effect of BSF-1, alone or together with other CSFs, on the growth of hematopoietic progenitor cells. Using adherent cell-depleted

Table 1. Hematopoietic Progenitor Cell Assays, Colony Types, and Factors Used

Hematopoietic Progenitor Cell Type	Definition of In Vitro Colonies	Factors Used* for Stimulation	Staining Procedures
CFU-GM: Restricted myelomonocyte progenitor cell	Clusters (10-50 cells) or colonies (>50 cells) of granulocytes and/or macrophages, scored after 7 days of incubation	BSF-1 30 U/mL G-CSF 10-200 U/mL IL 3 50 U/mL IL 1 5 U/mL	May-Grünwald-Giemsa
CFU-e: Restricted erythroid progenitor cell	Hemoglobin-containing clusters of more than 8 cells, scored after 2.5-3 days of incubation	EPO 0.1-1.0 U/mL BSF-1 30 U/mL	Benzidine May-Grünwald-Giemsa
BFU-e: Restricted primitive erythroid progenitor cell	Hemoglobin-containing single or multiple colonies of more than 50 cells, scored after 7 days of incubation	EPO 2.0 U/mL BSF-1 30 U/mL IL 3 50 U/mL	Benzidine May-Grünwald-Giemsa
CFU-mix: Multipotent hemopoietic progenitor cell	Colonies consisting of erythroid and megakaryocytic and/or myelomonocytic cells, scored after 7 days of incubation	EPO 2.0 U/mL BSF-1 30 U/mL IL 3 50 U/mL	Benzidine Acetylcholinesterase May-Grünwald-Giemsa
CFU-MK: Restricted megakaryocytic progenitor cell	Colonies of more than 3 megakaryocytes, scored after 7-8 days of incubation	IL 3 1-100 U/mL BSF-1 30 U/mL EPO 2.0 U/mL IL 1 5 U/mL FS7-20.16.8 CM 5%	Acetylcholinesterase

*The factors listed were used alone or in combination with each other, as described in results.

and T cell-depleted bone marrow cells in a modified agar culture technique,³⁷⁻³⁹ no significant cell proliferation was observed without growth factors after seven to 14 days of incubation. Therefore, effects of constituent production of growth factors in situ could be neglected in our culture system. Stimulation with IL 3, EPO, or G-CSF led to a proliferation of myelomonocytic and megakaryocytic, erythroid and granulocytic colonies respectively, as had been previously described for these factors.¹² In cultures stimulated with BSF-1 alone in concentrations of 30 to 1,000 U/mL, only a few small granulocyte/macrophage cell clusters and a few groups of two to three megakaryocytes developed. The effects of BSF-1 in combination with other growth factors is now described in the following sections.

Proliferation of granulocyte-macrophage progenitor cells (CFU-GM). First, to determine the maximal number of granulocyte/macrophage colonies that could be observed, IL 3, a powerful multi-CSF, was used as a growth factor. Stimulation with IL 3 (50 U/mL) induced a mean of 272 large colonies consisting of granulocytes and/or macrophages/20,000 cells plated in three different experiments. As described above, BSF-1 alone did not stimulate the proliferation of myeloid colonies; only four to seven granulocytic clusters of more than ten cells developed in these experiments.

We then tested the effects of BSF-1 together with G-CSF. After stimulation for seven days with various concentrations of G-CSF alone, a dose-dependent increase in the number of clusters (10 to 50 cells, Fig 1A) and of colonies (>50 cells, Fig 1B) consisting of mature granulocytes was observed. The addition of 30 U/mL of BSF-1 to various concentrations of G-CSF led to a significant increase in size and number of granulocytic clusters and colonies (Figs 1A and 1B). The use of higher concentrations of BSF-1 did not further increase the number of colonies derived from CFU-GM (Fig 2).

Fig 1. Role of BSF-1 in the stimulation of CFU-GM. Cultures were stimulated with various amounts of G-CSF alone or in combination with BSF-1 (30 U/mL) or IL 1 (5 U/mL). Clusters of 10 to 50 cells (A) and colonies of more than 50 cells (B) were counted after six days of incubation. Values represent the mean of three different experiments.

Fig 2. Effect of different concentrations of BSF-1 on proliferation of hematopoietic progenitor cells. Cultures were stimulated with various amounts of BSF-1 alone or in combination with G-CSF 200 U/mL (CFU-GM) or EPO 2.0 U/mL (BFU-e, CFU-mix, CFU-Mk). Colonies were counted after six days (CFU-GM) or seven days (BFU-e, CFU-mix, CFU-Mk) of incubation. Values represent the mean of triplicate cultures of one typical experiment.

Morphologically, most of these colonies consist of less differentiated granulocytic cells as compared to cells in colonies stimulated with G-CSF alone. In addition, some colonies with monocyte-macrophage features appeared. The addition of IL 1 to G-CSF had no enhancing effect on granulocytic colony formation (Figs 1A and 1B).

When cultures were stimulated with G-CSF and BSF-1 and incubated for 14 days, we observed development of macrophage colonies, whereas in control cultures containing medium alone, G-CSF or BSF-1 alone, no colony formation of any kind could be detected at this time (data not shown). The granulocytic colonies that had been present at seven days of culture have by 14 days degenerated and are no longer visible. The appearance of macrophage colonies at 14 days suggests that BSF-1 in the presence of G-CSF also can induce a commitment and proliferation of CFU-GM along the monocyte-macrophage cell lineage.

Monoclonal anti-BSF-1 antibody blocked the enhancing effect of BSF-1 on the formation of granulocytic colonies. In such cultures the number of colonies was reduced to values obtained with G-CSF alone (Table 2). This result indicates that the active principal in the BSF-1 preparations is, indeed, BSF-1.

Proliferation of mature erythroid progenitor cells (CFU-e).

CFU-e were stimulated with optimal (1.0 U/mL) or suboptimal (0.1 U/mL) amounts of recombinant erythropoietin (rEPO), as previously determined in titration experiments (data not shown), and numbers of erythroid clusters were evaluated in benzidine-stained preparations at 2.5 to three days of incubation (Fig 3). A few cell clusters consisting of nonhemoglobinized basophilic normoblasts developed in the absence of exogenously added EPO, most probably under the influence of the small amounts of EPO that are present in FCS. BSF-1 significantly enhanced the effect of 0.1 U/mL and 1.0 U/mL of EPO on CFU-e proliferation induced; the background proliferation of CFU-e without exogenous EPO was also increased by BSF-1 (Fig 3).

In cultures with BSF-1 alone or with 0.1 U/mL EPO $\pm$ BSF-1, only nonhemoglobinized basophilic normoblasts were observed, whereas in the presence of 1.0 U/mL EPO, BSF-1 enhanced the proliferation of fully hemoglobinized erythroid clusters. These data demonstrate that BSF-1 has an enhancing effect on the in vitro proliferation of mature erythroid progenitor cells and resembles the effects described for EPA.²³ As shown in Table 2, the enhancing activity of BSF-1 on CFU-e was abrogated by anti-BSF-1 antibody.

Proliferation of primitive erythroid (BFU-e) and multipotent (CFU-mix) progenitor cells. In contrast to CFU-e, BFU-e are evaluated by colony formation at seven days of culture, at which time clusters arising from CFU-e have degenerated. Under our culture conditions rEPO alone had almost no colony-stimulating activity on BFU-e (Fig 4). In cultures containing IL 3 alone, no hemoglobin-containing erythroid cells or morphologically recognizable normoblasts could be detected. Only pure granulocyte-macrophage and megakaryocyte colonies and colonies consisting of both of these cell types were observed. Thus a commitment to the erythroid cell line was not observed as a result of stimulation by IL 3 alone (data not shown). However, combination of EPO with IL 3 led to the proliferation of pure erythroid colonies and of mixed erythroid colonies (Fig 4). When BSF-1 was combined with EPO, a similar effect on BFU-e and CFU-mix was observed; both pure erythroid and mixed erythroid colonies were induced. Thus IL 3 and BSF-1 had comparable activities in allowing proliferation of BFU-e and of multipotent progenitor cells in the presence of EPO, as assessed in four different experiments (Fig 4). The effect of BSF-1 on BFU-e and CFU-mix was clearly detectable with BSF-1 10 U/mL and was not significantly enhanced with higher concentrations (Fig 2).

The mixed colonies, induced by EPO together with IL 3 or BSF-1, consisted of erythroid cells, megakaryocytes, and not clearly identifiable blast-like mononuclear cells. In the presence of IL 3, mixed colonies also contained granulocytes and macrophages, whereas BSF-1 together with EPO did not induce significant differentiation to the granulocytic cell lineage. In experiments in which the effect of the anti-BSF-1 antibody was examined, the effect of BSF-1 on BFU-e and CFU-mix was completely blocked by 11B11 (Table 2).

Proliferation of megakaryocyte progenitor cells (CFU-Mk). When bone marrow cells were incubated with BSF-1 alone, a few groups of three to four megakaryocytes and an increased number of single megakaryocytes could be identi-

fied by their positive staining for acetylcholinesterase (Fig 5A). IL 3 stimulates a substantial number of megakaryocyte colonies (Fig 5B). Recently a megakaryocyte-potentiating activity has been described that enhances megakaryocyte colony formation induced by IL 3.²⁵ Therefore several growth factors were tested for a megakaryocyte potentiating activity (Mk-PA) in costimulation with BSF-1 and with IL 3. IL 1, EPO, and the supernatant of the T cell hybridoma FS7-20.6.18, which has recently been shown to be a source of Mk-PA,²⁷ all significantly increased the number of megakaryocytic colonies obtained with BSF-1 (Fig 5A). This megakaryocyte-potentiating activity was also reflected in an increased cell number of the individual megakaryocyte colonies. IL 1 alone had no influence on megakaryocyte proliferation, whereas FS7-20.6.18-conditioned medium and EPO induced a small number of megakaryocyte colonies comparable to BSF-1. In cultures stimulated with BSF-1 and EPO, 14 of 63 megakaryocyte colonies shown in Fig 5A also contained erythrocytes. IL 1, FS7-20.6.18-CM, and EPO also significantly ($P < 0.05$) increased the number and size of megakaryocyte colonies obtained with IL 3 (10 U/mL or 100 U/mL). In the presence of EPO and IL 3, 25 of 139 colonies shown in Fig 5B contained both erythroid cells and megakaryocytes. These data demonstrate that the same potentiating factors have synergistic activities with both BSF-1 and IL 3, although at a different quantitative level. This suggests a Mk-CSF-like activity for BSF-1. The stimulating potency of BSF-1 on CFU-Mk was similar to its effects on CFU-GM and BFU-e (Fig 2). To determine whether BSF-1 also has Mk potentiating activity, we tested the capacity of BSF-1 to enhance the number of megakaryo-

cyte colonies that appear in response to IL 3 (Table 3). Even at suboptimal concentrations of IL 3, BSF-1 had no additive or synergistic effect on CFU-Mk proliferation, suggesting that BSF-1 lack Mk potentiating activity.

Anti-BSF-1 antibody abrogated the activity of BSF-1 on CFU-Mk, whereas the antibody had no influence on megakaryocyte colony formation induced by IL 3 (Table 2). The anti-BSF-1 antibody has also been used to further characterize the activity of FS7-20.6.18 CM. This supernatant has been shown to play a role in Ia induction on CFU-Mk,²⁷ analogous to an activity that is known for BSF-1 on B lymphocytes.^{4,5} Therefore to determine whether the activity of FS7-20.6.18 CM was due to BSF-1, we added anti-BSF-1 antibody. No blocking of the enhancement of CFU-Mk proliferation by FS7-20.6.18 CM in costimulation with IL 3 was observed, thus demonstrating that the MkPA of this T cell supernatant is not identical with BSF-1.

Depletion of B cells has no influence on the effect of BSF-1 on hematopoietic progenitor cells. Hematopoietic growth factors can exert their specific activity directly on the progenitor cell, or they can induce other cells like macrophages or T lymphocytes to release other growth factors that activate the particular target cell.⁴² To avoid these indirect effects, adherent cells and T lymphocytes were depleted in all experiments prior to the agar culture. Recently it has been described that activated B cells also can produce cytokines that affect in vitro stem cell proliferation.⁴³ Since BSF-1 is a known B cell activation factor, we attempted to exclude the possibility that the activity of BSF-1 on hematopoietic progenitor cells might be caused by an indirect effect on B lymphocytes in our bone marrow population. For this purpose we additionally depleted bone marrow cells of pre-B and B cells by incubation with anti-B220 antibody (RA33A16.1) and complement. The effects of BSF-1 and other growth factors on hematopoietic progenitor cells was tested on bone marrow cells depleted of B cells, adherent cells, and T cells and compared with cells depleted only of adherent cells and T cells. As shown in one typical experiment in Table 4, the number of colonies per culture increased after depletion of B220⁺ cells, probably due to an enrichment of hematopoietic progenitor cells. The activity of BSF-1 on all progenitor cells tested was not affected by the depletion of B and pre-B cells from the bone marrow.

Fig 3. Role of BSF-1 in the stimulation of CFU-e. Cultures were either unstimulated or stimulated with EPO alone or in combination with BSF-1 (30 U/mL). Erythroid clusters were counted in benzidine-stained preparations after 2.5 to three days of incubation. Values represent the mean of three different experiments.

DISCUSSION

BSF-1 was originally described as a lymphokine with multiple actions on B lymphocytes.¹⁻⁷ Recently it was

Fig 4. Role of BSF-1 in the stimulation of CFU-mix and BFU-e. Cultures were stimulated with either EPO alone or in combination with BSF-1 (30 U/mL) or IL 3 (50 U/mL). Mixed and pure erythroid colonies were counted in preparations stained with benzidine or for acetylcholinesterase after seven days of incubation. Mixed colonies contained mature erythroid cells and at least one other cell type (megakaryocytes and/or granulocytes/macrophages). Values represent the mean of four different experiments.

reported that the proliferation of T cell lines and mast cell lines is also affected by BSF-1.⁸⁻¹¹ The results presented in this study further extend the known activities of BSF-1 and provide evidence that it stimulates a broad spectrum of hematopoietic progenitor cells. Proliferative effects were detected on granulocyte-macrophage, erythroid, megakaryocyte, and multipotent progenitor cells. Such a wide range of activities was previously ascribed only to IL 3. In contrast to IL 3, however, the hematopoietic proliferative activities of BSF-1 were generally dependent on the presence of other factors.

A stimulatory effect of BSF-1 on proliferation of CFU-GM could only be detected in combination with G-CSF. Murine G-CSF at low-to-medium concentrations stimulates only a portion of the CFU-GM population to form colonies of small, mature granulocytes. G-CSF is also a potent granulocytic differentiation factor and it can initiate proliferation of multipotential and erythroid progenitor cells but is unable to sustain continued proliferation of these cells to result in colony formation.⁴⁴ The synergistic effect of BSF-1 with G-CSF could be explained by one of several mechanisms. It is possible that (1) BSF-1 enhances responsiveness of CFU-

Fig 5. Role of BSF-1 in the stimulation of CFU-Mk. Cultures were either unstimulated or stimulated with BSF-1 (30 U/mL) (A) or IL 3 (10 U/mL) or IL 3 (100 U/mL) (B). To these cultures, medium alone, IL 1 (5 U/mL), FS7-20.6.18 CM 5% or EPO (2.0 U/mL) were added. Mk colonies were counted in acetylcholinesterase-stained preparations after seven days of incubation. Values represent the mean of three different experiments. The differences in colony number between cultures stimulated with BSF-1 or IL 3 alone and cultures stimulated with BSF-1 or IL 3 and one of the additional factors (IL 1, FS7-20.6.18, or EPO) were analyzed by the two-tailed Dunnett test. The *P* values for the comparison of BSF-1 alone and BSF-1 plus each of the costimulants (individually or as a group) were <0.01 . For the similar comparison for IL 3 (10 U/mL) or IL 3 (100 U/mL), the *P* values were all <0.05 .

GM to G-CSF, possibly by increasing the expression of receptors for G-CSF; (2) BSF-1 prevents terminal differentiation of progeny of CFU-GM and augments, therefore, their proliferation; or (3) G-CSF induces responsiveness of myeloid cells to BSF-1. In preliminary experiments we observed that BSF-1 can sustain the survival of CFU-GM in agar or liquid culture over several days (data not shown). Furthermore, a proliferation of macrophage colonies is also induced by BSF-1 in presence of G-CSF, a factor predominantly specific for cells of the granulocyte lineage.⁴⁴ These observations and the finding that the myeloid cell line DA-1 expresses BSF-1 receptors⁴⁵ support the possibility that BSF-1 directly stimulates CFU-GM.

Clear evidence for a direct effect of BSF-1 on progenitor cells is provided by its activity on BFU-e and CFU-mix. It is generally accepted that EPO represents the growth factor for the more mature erythroid progenitor cell, CFU-e, whereas primitive erythroid progenitor cells, BFU-e, require another activity, frequently designated as "burst-promoting activity," for proliferation. This activity has previously been shown to be provided by IL 3,¹⁵ erythroid potentiating activity (EPA),²³ and to some extent by G-CSF⁴⁴ and GM-CSF.^{17,19,20} IL 3 promotes proliferation of BFU-e and CFU-mix. Progeny of such IL 3-stimulated BFU-e and CFU-mix can then be induced by EPO to further growth and differentiation into mature erythrocytes. However, EPO does not appear to be necessary for initial proliferation of the immature progenitors.^{15,22,38} Therefore it has been suggested that EPO receptors are expressed on intermediate cells between BFU-e and CFU-e. We demonstrate here that BSF-1 and EPO together can also stimulate the growth of BFU-e to form erythroid colonies and of CFU-mix with a predominant differentiation toward erythroid and megakaryocytic cells. Since EPO by itself is believed to have no capacity to stimulate BFU-e and

CFU-mix, BSF-1, like IL 3, must be another primary stimulatory factor that prepares the progenitor cells to respond to EPO. In contrast to IL 3, however, BSF-1 alone does not appear to stimulate sustained proliferation of BFU-e and of CFU-mix, but EPO and BSF-1 are both required during the entire culture period for optimal growth of erythroid colonies. It can therefore be assumed that BSF-1 works mainly as an activation factor on BFU-e and CFU-mix and renders them sensitive to EPO, possibly by inducing the expression of functional EPO receptors.

In addition to its activity on BFU-e, BSF-1 enhances the proliferation of CFU-e in the presence of suboptimal and of optimal amounts of EPO. The enhancing effect of BSF-1 on the response of CFU-e and BFU-e to EPO resembles the activity of EPA on human and mouse erythroid progenitors. EPA has recently been purified from a HTLV-II-infected human T cell line and has been molecularly cloned.^{23,24} A comparison of the cDNA sequences of EPA²⁴ and the human analogue of BSF-1⁴⁶ demonstrates that these are distinct entities. EPA also appears to differ from BSF-1 in that its described activities are limited to erythroid lineage cells.²³

In assays for megakaryocytic progenitor cells, we found that BSF-1 exerted striking effects on colony formation. Previous studies had indicated that murine CFU-Mk are regulated in vitro by Mk-CSF and Mk potentiating activity. Mk-CSF appears to act directly on CFU-Mk cells and is now considered to be identical with IL 3²⁶; GM-CSF has also some activity on CFU-Mk.¹⁶ Mk potentiating activity (Mk-PA) is less well defined; it enhances the number and size of Mk colonies in the presence of IL 3 and acts on immature megakaryocytes rather than on CFU-Mk. Mk-PA is found in several crude supernatants from bone, bone marrow, lung and spleen cells,⁴⁷ and in supernatants of the macrophage line P388D1²⁶; recently a T cell hybridoma designated FS7-20.6.18 has been described to produce MkPA.²⁷

IL 3 by itself stimulates the production of a large number of Mk colonies. By contrast, BSF-1 alone induced only sparse small groups of megakaryocytes. Nevertheless both IL 3 and BSF-1 show synergy with the MkPA found in FS7-20.6.18 CM. Furthermore we showed that IL 1 and EPO synergize with IL 3 and thus should be regarded as having Mk-PA. Both these agents also synergize with BSF-1. This suggests that BSF-1, although stimulating by itself the appearance of only a small number of Mk colonies, shares some activity with IL 3 on CFU-Mk. The finding that BSF-1 and IL 3 do not synergize with one another also supports the concept that

Table 4. Depletion of B220⁺ Cells Does Not Inhibit Hemopoietic Progenitor Cell Proliferation Induced by BSF-1

they have a similar activity. Thus we would identify BSF-1 as having some Mk-CSF activity.

The MkPA of pure IL 1 and EPO have not previously been described. However, supernatants of the P388D1 cell line, a major component of which is IL 1, have been described to enhance Mk colony formation.²⁶ Our experiments using recombinant IL 1 confirm that the megakaryocyte-enhancing activity in P388D1 supernatant is most likely IL 1. Crude preparations of EPO have been used as primary stimulus of CFU-Mk⁴⁸ and as potentiating factor together with IL 3 (D. Geissler, manuscript in preparation). In another study a small level of Mk stimulatory activity was found in only one of four preparations of biochemically purified EPO.⁴⁹ We here present clear evidence that purified, recombinant EPO has an effect on megakaryocyte colony formation in the presence of IL 3 or BSF-1. Small but constant numbers of Mk colonies were also detected in cultures stimulated with EPO alone, demonstrating a direct effect of EPO at least on a subpopulation of CFU-Mk.

In conclusion, BSF-1 affects the *in vitro* proliferation of myeloid, erythroid, megakaryocyte, and multipotent progenitor cells. The nature of action on these hemopoietic cells is not yet known. It can be assumed that BSF-1 works directly on the progenitor cell population, since the depletion of adherent cells, T cells, and B cells did not result in a diminished colony proliferation. Active cell proliferation and colony formation, however, can only be observed when BSF-1 is combined with an additional factor, a property that has also been observed for BSF-1 as B cell^{2,3} and mast cell-stimulating factor^{8,9,11} and in its ability to stimulate proliferation by resting T cells.⁵⁰ The factors costimulating with BSF-1 are G-CSF for CFU-GM; EPO for CFU-e, BFU-e, and CFU-mix; and factors with MkPA for CFU-Mk proliferation. All these proteins are regarded to influence predominantly later stages of hemopoiesis, whereas certain progenitor cells (BFU-e, CFU-mix, and most CFU-Mk) do not respond to their respective factors alone. However, the

combination of these factors with BSF-1 results in a clonal proliferation and colony formation *in vitro*, suggesting a primary effect of BSF-1 on such progenitor cells. It can therefore be hypothesized that BSF-1 represents an activation factor for early hemopoietic progenitor cells and prepares the progenitor cells to respond to specific growth or differentiation factors. The effects of BSF-1 on hemato-poietic progenitor cells are reminiscent of a recently described pre-B cell stimulatory activity that has synergistic effects with IL 3, GM-CSF, and M-CSF.⁵¹ However, anti-BSF-1 antibody does not neutralize this activity, suggesting that this pre-B cell stimulating factor and BSF-1 are different entities.⁵¹

The concepts of action of BSF-1 on hematopoietic progenitor cells are clearly in keeping with the capacity of BSF-1 to act on resting B cells to enhance their subsequent responsiveness to anti-IgM antibodies^{2,3} and to LPS and with the costimulatory action of BSF-1 and phorbol esters to render T cells responsive to interleukin 2 (IL 2).⁵⁰ However, BSF-1 also possesses clear growth-promoting activities on T cells⁵⁰ and B cells.⁵² It stimulates DNA synthesis in T cell blasts and certain long-term T cell lines⁸⁻¹⁰ to enter the S phase of the cell cycle by an IL 2-independent mechanism. BSF-1 may prove to act as both a physiologic activation factor and growth factor in the regulation by T cells of hematopoietic cell growth.

ACKNOWLEDGMENT

We wish to thank Dr J. Ihle and P. Marrack for supplying purified IL 3 and T cell hybridoma and supernatants, respectively. Recombinant IL-1 α and recombinant hG-CSF was generously provided by Hoffmann LaRoche (Nutley, NJ) and Amgen (Thousand Oaks, CA), respectively. The important help of Dr Robert Fine during the initial phase of this study is appreciated. We thank Dr David Alling for his advice and the performance of the statistical analysis. We gratefully acknowledge the editorial assistance of Shirley Starnes.

Lactoferrin Binding by Leukemia Cell Lines

By Yasuaki Yamada, Tatsuhiko Amagasaki, Donald W. Jacobsen, and Ralph Green

Monocytes and macrophages have receptors for the iron-binding protein lactoferrin. Lactoferrin acts as a potent inhibitor of granulocyte-macrophage colony stimulating factor production when it binds to these cells. Using a rosette assay and immunofluorescence, we have shown that cultured leukemia cells, including the human erythroid leukemia cell line K562, also have lactoferrin binding sites. The number of binding sites on K562 cells was estimated using soluble ^{59}Fe -lactoferrin. Inhibition studies demonstrate that lactoferrin binding sites are distinct and unrelated to receptors for transferrin or the Fc portion of IgG, which are present on K562 cells. However, electrostatic

forces may be important for lactoferrin binding, since other polycationic proteins (eg, protamine) inhibit lactoferrin binding. Prior treatment of K562 cells with trypsin nearly abolishes lactoferrin binding. However, these cells recover their ability to bind lactoferrin when trypsin is removed. Unlike transferrin receptors, the expression of lactoferrin binding sites is not regulated by cellular iron status. Cytosine arabinoside arrests the proliferation of K562 cells and simultaneously leads to a reduction in lactoferrin surface binding, suggesting that lactoferrin binding may be dependent on cell proliferation.

LACTOFERRIN,* a cationic glycoprotein that binds two atoms of ferric iron per molecule,¹ is present in high concentration in milk (1 mg/mL),^{2,3} other body secretions,^{4,5} and in secondary granules of myeloid cells (3 $\mu\text{g}/10^6$ neutrophils),^{6,8} but is scarcely detectable in the serum (less than 1 $\mu\text{g}/\text{mL}$).⁹ It has many biochemical similarities to transferrin,¹⁰⁻¹² which is present in plasma (2 to 4 mg/mL)¹³ and other body fluids. A major biological role for transferrin as an iron transport and delivery protein has been defined. Immature erythroid cells, activated lymphocytes, and neoplastic cells, which require iron for hemoglobin synthesis or replication, take up iron efficiently through the specific receptor for transferrin.¹⁴⁻¹⁸ On the other hand, the biological significance of lactoferrin remains obscure. One of its roles is in the regulation of normal myelopoiesis. Lactoferrin binding to the surface of monocytes through a putative specific receptor results in suppression of the release of granulocyte-macrophage colony stimulating factor.¹⁹ Another suggested role is as a bacteriostatic or bactericidal agent.^{4,20} Apo-lactoferrin depresses the multiplication of iron-dependent microbial strains. Little is known about the relation between lactoferrin and neoplastic cells. By applying a rosette-

forming assay that was developed in our laboratory,²¹ we have found that neoplastic cells also express lactoferrin binding sites similar to those reported for monocytes or macrophages. We report here the nature of lactoferrin binding to cultured leukemia cells.

MATERIALS AND METHODS

Cell preparation. K562 cells, a human erythroid leukemia cell line, were used to analyze the kinetics of lactoferrin binding. Cells were grown in RPMI 1640 medium supplemented with 5% heat-inactivated fetal bovine serum, 100 U/mL penicillin, 100 $\mu\text{g}/\text{mL}$ streptomycin, and 0.25 $\mu\text{g}/\text{mL}$ fungizone (Irvine Scientific, Santa Ana, CA). MOLT-4 cells and CCRF-CEM cells (human T lymphoblastic leukemia cell lines), U937 cells (human histiocytic lymphoma cell line), HL-60 cells (human acute promyelocytic leukemia cell line), CCF-Y1 cells (a human B cell line established in our laboratory from a patient with Ph¹ negative juvenile chronic myelocytic leukemia), Raji cells (human Burkitt lymphoma cell line), and L1210 cells (mouse B lymphocytic leukemia cell line) were also used and were grown under similar conditions but with 10% fetal bovine serum medium. All experiments were conducted using cells at growth densities of 3 to 5 $\times 10^5$ cells/mL (logarithmic phase). Cells were washed once with RPMI 1640 + 0.5% bovine serum albumin (fraction V; Sigma Chemical Co, St Louis), resuspended in the same medium at a cell density of 1 $\times 10^6/\text{mL}$, and used for rosette formation.

Mononuclear cells were separated from heparinized normal blood by a density-gradient centrifugation technique using Ficoll-Hypaque (FH; Pharmacia, Piscataway, NJ). Cells were then passed through a nylon-wool column²² to enrich T lymphocytes. The resultant T lymphocytes were activated by stimulation with concanavalin A (Con A; Sigma) for 96 hours and evaluated for lactoferrin binding.

Lactoferrin and transferrin. Purified human apo-lactoferrin from colostrum (Calbiochem-Behring, La Jolla, CA) and human apo-transferrin (Sigma) were saturated with iron according to the method described by Bates and Schlabach.^{21,23} Iron saturation was confirmed spectrophotometrically by an increase in absorbance at 460 nm ($A_{460}/A_{280} = 0.045$ to 0.048 for fully saturated transferrin).²⁴ Monoclonal antibodies (MoAbs) against the human transferrin receptor (42/6 and B3/25)²⁵ were generously supplied by Dr Ian Trowbridge (Salk Institute, La Jolla, CA). OKT9 antihuman transferrin receptor antibody was purchased from Ortho Diagnostic Systems (Raritan, NJ).

Lactoferrin coating of bovine red blood cells and rosetting procedure. Lactoferrin was coated on bovine red blood cells (B-RBC) using CrCl_3 according to the method described originally for the protein A hemolytic plaque assay²⁶ and modified subsequently by

*Lactoferrin and transferrin refer to the diferric forms, unless otherwise stated.

this laboratory for transferrin-coated B-RBC.²¹ Successful coupling of lactoferrin on B-RBC was confirmed with fluorescein isothiocyanate (FITC)-labeled antilactoferrin antibody (Cappel Worthington Biochemicals, Malvern, PA). Apo-lactoferrin, transferrin, or albumin-coated B-RBC were prepared similarly, using the same concentrations of protein. Cultured neoplastic cells or T lymphocytes (1×10^6 /mL in 0.25 mL) were mixed with 0.1 mL of lactoferrin, transferrin, or albumin-coated B-RBC (0.5% packed cell volume) in U-bottom 12 $\times$ 75-mm tubes (Falcon #2054, Oxnard, CA). The mixtures were centrifuged at $30 \times g$ for three minutes and then incubated at 37°C for 45 minutes (except for the time-course study). The pellets were carefully resuspended, and rosette formation was estimated visually using a hemocytometer. More than 200 cells were counted, and those cells binding more than three B-RBC on their surface were considered positive for rosette formation. All experiments were performed in triplicate.

Immunofluorescence assay. Lactoferrin binding was also evaluated by an immunofluorescence assay using soluble lactoferrin. After washing three times with PBS, 1×10^6 pelleted cells were incubated with 100 μ L of lactoferrin solution (50 μ g/mL in PBS) at 4°C for 60 minutes. The treated cells were washed three times with PBS, and then incubated with 50 μ L of a 1/20 dilution of FITC-conjugated rabbit antihuman lactoferrin antibody (F(ab')₂ fraction, Cappel Labs). After washing three times with PBS, the labeled cells were examined using a fluorescence-activated cell sorter.

⁵⁹Fe-lactoferrin binding assay. Apo-lactoferrin was saturated with ⁵⁹Fe (⁵⁹FeCl₃, New England Nuclear, Boston) by the method used for preparing nonradiolabeled diferric-lactoferrin.^{21,23} K562 cells (1×10^6) suspended in Hank's balanced salt solution (HBSS) were incubated at 4°C for 60 minutes with various concentrations of ⁵⁹Fe-lactoferrin. After incubation cells were washed three times with HBSS, and radioactivity was measured in a gamma spectrometer.

Benzidine staining. K562 cells were cultured in the presence of 3.6×10^{-7} mol/L cytosine arabinoside (Sigma) to induce erythroid differentiation²⁷ for assessment of differentiation-associated change in lactoferrin binding ability. Hemoglobin synthesis in these cells was estimated by benzidine staining.²⁷ The proportion of cells that synthesized hemoglobin (stained blue) was assessed by light microscopy.

Other chemicals. Deferoxamine mesylate (Desferal, CIBA Pharmaceutical Co, Summit, NJ) or ferrie ammonium citrate (Sigma) were dissolved in distilled water and added to culture media at final concentrations of 1×10^{-5} mol/L and 10 μ g/mL respectively to determine the effect of iron content of the culture solution on the expression of transferrin receptor and lactoferrin binding sites. Cells treated with 0.25% trypsin solution (Irvine Scientific) for one minute at 37°C, cells treated with 2 mg/mL of deoxyribonuclease I or ribonuclease A (DNase or RNase, Sigma) for one hour at room temperature, and cells treated with 0.1 U/mL of neuraminidase (Calbiochem-Boehringer) for 20 minutes at 37°C were used to assess the susceptibility of lactoferrin binding sites to digestion by these enzymes. Human IgG (Sigma) was incubated for 30 minutes at 60°C to prepare heat-aggregated IgG for use in experiments to study inhibition of rosette formation. Human milk lysozyme and salmon protamine (Sigma) were also used to study the specificity of lactoferrin binding.

RESULTS

Time-course study of rosette formation. Mixtures of K562 cells and lactoferrin-, apo-lactoferrin- or albumin-coated B-RBC were incubated for up to 90 minutes at 37°C. Rosette formation with lactoferrin-coated B-RBC increased rapidly and reached a plateau after 45 minutes incubation (Fig 1). Rosette formation was lower with apo-lactoferrin-

Fig 1. Time course of rosette formation. K562 cells were incubated with lactoferrin- (●—●), apo-lactoferrin (○—○), or albumin- (△—△) coated B-RBC. Each point is the mean of three assays; vertical bars indicate standard deviations.

coated B-RBC. Control albumin-coated B-RBCs did not form rosettes throughout the incubation time.

Determination of lactoferrin binding sites by Scatchard analysis. ⁵⁹Fe-radiolabeled lactoferrin showed saturable binding to K562 cells (Fig 2). A Scatchard plot analysis of these data showed maximum binding of 4.9×10^7 molecules per cell; the dissociation constant was 7.4×10^{-6} mol/L. A competition assay using a tenfold excess of unlabeled lactoferrin was also attempted but was unsuccessful due to the technical problem caused by cell aggregation at lactoferrin concentrations greater than 2.5 mg/mL.

Specificity of rosette-forming assay for detection of lactoferrin binding sites. To test the specificity of the rosette-forming assay, K562 cells were preincubated with either soluble lactoferrin, transferrin, or MoAbs against transferrin receptor for 30 minutes at room temperature before addition of lactoferrin-coated B-RBC. Rosette formation was inhibited by prior treatment with soluble lactoferrin in a dose-dependent manner (Fig 3). Soluble apo-lactoferrin also inhibited rosette formation almost to the same extent as did soluble lactoferrin (Table 1). However, neither transferrin nor three types of MoAbs against transferrin receptor inhibited rosette formation with lactoferrin-coated B-RBC (Table 1); all inhibited rosette formation with transferrin-coated B-RBC at the same concentrations.²¹ Heat-aggregated IgG at a concentration of 64 μ g/mL, which is sufficient to fully saturate all Fc receptors on K562 cells,²⁸ did not inhibit rosette formation (Table 1). Since lactoferrin is a cationic protein (pI = 8.7),²⁹ nonspecific electrostatic binding to the cell surface membrane was considered. To investigate this possibility, we used two kinds of cationic proteins in competition studies: human milk lysozyme and salmon protamine. Lysozyme caused no inhibition, but protamine substantially inhibited rosette formation. Furthermore, neuraminidase, an enzyme that cleaves membrane surface sialic acid resulting in decreased cell surface negative charge, also partially inhibited rosette formation.

Trypsin sensitivity of lactoferrin binding sites. K562 cells were examined for rosette formation with lactoferrin-coated B-RBC before and after digestion with trypsin. In three experiments, rosette formation decreased markedly

Fig 2. Dose-response binding of ⁵⁹Fe-radiolabeled lactoferrin to K562 cells. The mean of three experiments is shown. A Scatchard plot analysis (inset), indicates that 4.9×10^7 molecules are bound to each K562 cell at saturation. The dissociation constant (K_d) derived from the concentration of free ligand at half saturation of the binding sites is 7.4×10^{-6} mol/L.

following trypsin digestion (from $82.9\% \pm 0.6\%$ to $11.8\% \pm 3.9\%$) but recovered almost to pretreatment levels following culture of the digested cells for five hours at 37°C in culture medium without trypsin ($74.6\% \pm 2.0\%$). Trypsin sensitivity of lactoferrin binding by MOLT-4 cells was also shown using the immunofluorescence assay (Fig 4). Binding

Fig 3. Inhibition of rosette formation by soluble lactoferrin. K562 cells were pretreated with soluble lactoferrin before rosette formation. Each point is the mean of three assays; vertical bars indicate standard deviations.

Table 1. Specificity of Rosette-Forming Assay

Treatment of K562 Cells*	Inhibition of Rosette Formation (%) Mean $\pm$ SD (n = 3)
Lactoferrin (64 $\mu\text{g}/\text{mL}$)	74.0 ± 1.8
Apo-lactoferrin (64 $\mu\text{g}/\text{mL}$)	77.9 ± 3.6
Transferrin (64 $\mu\text{g}/\text{mL}$)	-1.9 ± 6.8
Apo-transferrin (64 $\mu\text{g}/\text{mL}$)	-3.1 ± 9.0
MoAbs against transferrin receptor	
42/6 (1 $\mu\text{g}/\text{mL}$)	9.1 ± 3.9
B3/25 (1 $\mu\text{g}/\text{mL}$)	3.4 ± 5.9
OKT9 (1 $\mu\text{g}/\text{mL}$)	5.4 ± 8.7
Heat-aggregated human IgG (64 $\mu\text{g}/\text{mL}$)	-1.5 ± 3.3
Cationic proteins	
Human milk lysozyme (64 $\mu\text{g}/\text{mL}$)	-1.9 ± 1.0
Salmon protamine (64 $\mu\text{g}/\text{mL}$)	44.6 ± 8.9
Neuraminidase (0.1 U/mL)	31.5 ± 4.0

*K562 cells were pretreated with these agents before rosette formation for 30 minutes at room temperature except for neuraminidase treatment, which was performed at 37°C .

Fig 4. Trypsin sensitivity of lactoferrin binding sites. Labeled MOLT-4 cells (—) were processed on a fluorescence-activated cell sorter and compared with control cells (---) treated with FITC-conjugated antibody only. Nontreated cells (A), trypsin-digested cells (B), DNase-treated cells (C), and RNase-treated cells (D) were analyzed for lactoferrin binding.

was almost completely abrogated by trypsin digestion (Fig 4B). DNase did not remove but rather enhanced lactoferrin binding (Fig 4C). Interestingly, RNase caused slight inhibition of lactoferrin binding (Fig 4D).

Influence of iron availability on the expression of lactoferrin binding. K562 cells were cultured up to 96 hours in the presence of the iron chelator deferoxamine (1×10^{-5} mol/L) or 10 $\mu\text{g/mL}$ ferric ammonium citrate. At various times lactoferrin and transferrin binding by these cells was assessed with the rosette-forming assay. Proliferation status of K562 cells was not affected by either agent at these concentrations, and the doubling times of these cells were similar to untreated control cells. Rosette formation with transferrin-coated B-RBC increased two to three times following deferoxamine treatment but decreased to less than one-half following addition of ferric ammonium citrate (Fig 5A). However, rosette formation with lactoferrin-coated B-RBC was not influenced by these agents (Fig 5B).

Influence of cell proliferation status on expression of lactoferrin binding. K562 cells were cultured with cytosine arabinoside (C-ara) and examined for rosette formation with lactoferrin-coated B-RBC at 24-hour intervals. The culture solution was replaced by fresh media containing C-ara every other day. Cell proliferation ceased after 24 hours in C-ara medium, but the viability remained greater than 90%. The proportion of benzidine-positive cells increased daily and reached 77.7% at 144 hours, indicating maturation to hemoglobin-producing cells. There was a corresponding inverse decline in rosette formation rate (Fig 6). This decrease in lactoferrin binding could be curtailed by removing C-ara from the culture media.

Lactoferrin binding sites on various cells. Expression of lactoferrin binding sites was examined on other neoplastic cell lines as well as on normal blood lymphocytes before and after activation with Con A (Table 2). The immunofluorescence assay was always more sensitive than the rosette-forming assay. Four (K562, MOLT-4, L1210, and CCF-Y1) of eight cell lines examined showed abundant lactoferrin binding sites. The rosette-forming assay failed to detect lactoferrin binding sites on activated T lymphocytes, but the immunofluorescence assay showed that approximately one half of activated T lymphocytes display lactoferrin binding.

Fig 6. Effects of C-ara on the expression of lactoferrin binding sites. Rosette formation was performed on K562 cells cultured in the presence of C-ara (●—●). For some cells C-ara was removed at 48 hours, and culture was continued without C-ara (○—○). Each point is the mean of three assays; vertical bars indicate standard deviations.

DISCUSSION

Although more than 25 years have passed since the iron-binding protein lactoferrin was found in milk,³ its biological functions are still poorly understood. Receptor-like binding of lactoferrin to human peripheral monocytes has been described.^{30,31} Furthermore, it has been reported that lactoferrin has an inhibitory effect on the release of granulocyte-macrophage colony stimulating factor (GM-CSF) from monocytes and macrophages.¹⁹ Few studies have been done on the relation between lactoferrin and neoplastic cells. Two recent articles have shown that lactoferrin is an essential nutrient for the growth of neoplastic cell lines in serum-free medium. Growth stimulation of Bri 7 cells, a human B lymphocytic leukemia cell line, was greater with lactoferrin than with transferrin.³² Similarly, growth of HT29, a human colon adenocarcinoma cell line, was also stimulated by

Fig 5. Influence of iron content of culture media on the expression of transferrin receptor (A) and lactoferrin binding sites (B). K562 cells were cultured with deferoxamine (△—△) or ferric ammonium citrate (●—●) for varying times up to 96 hours and compared with control cells (○—○) for their transferrin and lactoferrin binding ability. Each point is the mean of three assays; vertical bars indicate standard deviations.

Table 2. Lactoferrin Binding by Neoplastic Cell Lines and Normal T Lymphocytes

Cells	Rosette Formation % Mean $\pm$ SD (n = 3)	Immunofluorescence Assay (%)
K562	90.0 $\pm$ 3.8	97.7
MOLT-4	21.3 $\pm$ 5.2	67.3
L1210	28.9 $\pm$ 3.3	ND
CCF-Y1	13.0 $\pm$ 1.4	91.8
CCRF-CEM	2.9 $\pm$ 0.5	ND
HL-60	0.7 $\pm$ 0.7	9.7
U937	0	14.0
Raji	0	4.9
Resting T lymphocytes	0	2.8
Mitogen-stimulated T lymphocytes	0	55.4

lactoferrin.³³ The effect was more pronounced in the presence of iron. These reports led us to study lactoferrin binding sites on neoplastic cells.

In the present studies we used a rosette-forming assay to detect lactoferrin binding. Rosette formation rate was greater with lactoferrin-coated than with apo-lactoferrin-coated B-RBC, suggesting a higher binding affinity of iron-saturated lactoferrin. Although differences in the quantity of protein coating cannot completely be excluded, it is unlikely that this is the cause of the discrepancy, since the same concentration of lactoferrin or apo-lactoferrin was used for coating. By analogy, iron-saturated transferrin has higher binding affinity to its receptor than apo-transferrin.³⁴⁻³⁶ The transferrin molecule becomes more compact and spherical after it has bound iron,^{34,37,38} and this may be advantageous for receptor binding. On the other hand, rosette formation with lactoferrin-coated B-RBC was inhibited by soluble lactoferrin irrespective of its iron content, suggesting that low affinity binding is sufficient to suppress rosette formation. However, lactoferrin-coated B-RBC rosette formation was not inhibited by transferrin, MoAbs against the transferrin receptor, or heat-aggregated human IgG. This indicates that lactoferrin occupies binding sites different from those for either the transferrin receptor or the Fc receptor for IgG, which are both present on K562 cells.²⁸

The number of lactoferrin binding sites on K562 cells was estimated by Scatchard analysis using ⁵⁹Fe-lactoferrin. Binding of ⁵⁹Fe-lactoferrin was saturable, and the number of binding sites per cell (4.9×10^7), though high, agrees with figures reported for adherent mononuclear cells (3.3×10^7 per cell) and nonrosetting lymphocytes (2.5×10^7 per cell) prepared from normal human blood.³⁰ Because of problems with cell aggregation that we encountered at high lactoferrin concentrations, it was not possible to eliminate nonspecific binding, so that our figure is likely an overestimate of the number of binding sites.

Since lactoferrin is a cationic protein (pI = 8.7),²⁹ we considered that binding to the negatively charged cell surface might be of a nonspecific electrostatic nature. We therefore pretreated K562 cells with two other cationic proteins to block surface-negative charges. The more cationic lysozyme (pI = 10.5 to 11.0)³⁹ did not inhibit lactoferrin-B-RBC rosette formation. However, protamine caused considerable

inhibition, although the inhibitory activity was less than that of soluble lactoferrin. Sialic acid, one of the major sources of surface negative charge, was removed by neuraminidase treatment⁴⁰ of K562 cells and resulted in a decrease of rosette formation. Taken together these findings suggest that electrostatic factors are intimately involved in lactoferrin binding to cells. Similar electrostatic factors have been implicated in the binding of lactoferrin to macrophages and liver reticuloendothelial cells. Lactoferrin binds to alveolar macrophages in competition with the other cationic neutrophil granule glycoproteins, elastase and cathepsin G.⁴¹ Removal of sialic acid from lactoferrin increases its binding affinity to mouse peritoneal macrophages.⁴² Moreover, based on a study of lactoferrin uptake by the liver, the possible existence of common binding sites for certain cationic proteins on liver reticuloendothelial cells has been postulated.⁴³ The lactoferrin binding sites we have demonstrated on neoplastic cell lines are similar in some respects to the lactoferrin binding sites described on macrophages and liver reticuloendothelial cells. However, there are also differences, such as the sensitivity to trypsin digestion. We found marked sensitivity to trypsin digestion of lactoferrin binding by neoplastic cells. In contrast, lactoferrin binding by human peripheral blood monocytes is somewhat resistant to trypsin digestion.⁴⁴ A further difference is the sensitivity to DNase and RNase. Lactoferrin binding sites on neoplastic cells were resistant to DNase but were partially sensitive to RNase, suggesting that lactoferrin binding sites may be RNase-susceptible acidic groups present on the cell surface.⁴⁰ In contrast to neoplastic cells, lactoferrin binding sites on normal human monocytes are sensitive to DNase treatment.⁴⁴

Transferrin receptor expression of cultured cells is regulated by the iron concentration of the culture medium. An iron chelator, deferoxamine, increases the number of transferrin receptors, whereas excess iron decreases transferrin receptor expression.^{24,45,46,47,48} We confirmed this observation by finding a good inverse correlation between iron supply and transferrin-receptor expression using our rosette-forming assay. Lactoferrin shows close structural homology to transferrin at the iron binding site, but unlike transferrin, lactoferrin binding to cells was not influenced by cellular iron status. This finding supports the view that K562 cells cannot take up iron from lactoferrin even though cells can bind and internalize lactoferrin (unpublished observation).

Four of eight leukemic cell lines as well as activated T lymphocytes showed lactoferrin binding, but resting T lymphocytes did not. Similarly, receptor-like binding of lactoferrin to fresh leukemia cells, but not to normal lymphocytes or platelets has been reported.⁴⁹ Furthermore, we were able to demonstrate diminished expression of lactoferrin binding by C-ara treatment of K562 cells. These results seem to indicate that there is a close relationship between lactoferrin binding and cell proliferative status. Although monocytes and activated lymphocytes also have lactoferrin binding sites, analysis in conjunction with other cell markers may prove useful for the identification of leukemic cells in blood or neoplastic cells in body fluids suspected to contain metastatic tumor.

CFU-GM Content of Bone Marrow Graft Correlates With Time to Hematologic Reconstitution Following Autologous Bone Marrow Transplantation With 4-Hydroperoxycyclophosphamide-Purged Bone Marrow

By Scott D. Rowley, Michael Zuehlis, Hayden G. Braine, O. Michael Colvin, Janice Davis, Richard J. Jones, Rein Saral, Lyle L. Sensenbrenner, Andrew Yeager, and George W. Santos

Autologous bone marrow transplants (BMTs) can repopulate the hematologic system of patients treated with marrow-ablative chemotherapy and/or radiotherapy. However, treatment of the bone marrow graft to eliminate residual tumor cells prior to reinfusion can delay the return of peripheral blood elements, presumably from damage to or loss of hematopoietic stem cells responsible for hematologic recovery. To develop a model predictive of hematologic recovery, we studied the progenitor cell contents of 4-hydroperoxycyclophosphamide (100 $\mu\text{g}/\text{mL}$)-purged bone marrow grafts of 40 consecutive patients undergoing autologous BMT at this center. Granulocyte-macrophage colonies (CFU-GM) were grown from all grafts after treat-

ment with this chemotherapeutic agent, but erythroid (BFU-E) and mixed (CFU-GEMM) colonies were grown from only 44% and 33% of the grafts respectively. The recovery of CFU-GM after purging ranged from 0.07% to 23%. The logarithm of CFU-GM content of the treated grafts was linearly correlated with the time to recovery of peripheral blood leukocytes ($r = -0.80$), neutrophils ($r = -0.79$), reticulocytes ($r = -0.60$), and platelets ($r = -0.66$). The CFU-GM content of purged autologous bone marrow grafts may reflect the hematopoietic stem cell content of the grafts and thus predict the rate of hematologic recovery in patients undergoing autologous BMT.

©1987 by Grune & Stratton, Inc.

AUTOLOGOUS bone marrow transplantation (BMT) permits the administration of intensive cytotoxic regimens to patients with a variety of malignancies who do not have human leukocyte antigen (HLA)-matched bone marrow donors.¹⁻⁵ For tumors that originate in or frequently metastasize to the bone marrow, techniques of purging residual malignant cells from the harvested bone marrow graft prior to reinfusion have been developed and used in clinical trials.⁶ This center has studied autologous BMT for the treatment of acute leukemia using bone marrow grafts incubated ex vivo with 4-hydroperoxycyclophosphamide (4-HC) before cryopreservation and subsequent reinfusion.^{7,8} In a phase I trial,⁷ a concentration of 100 $\mu\text{g}/\text{mL}$ 4-HC was determined to be the maximum that would allow consistent hematologic reconstitution. Many patients regained hematopoietic function despite the absence of detectable CFU-C in the treated marrow grafts, and CFU-C determinations did not appear to be predictive of hematologic reconstitution in these patients. However, the time to reconstitution appeared to increase with increasing 4-HC concentrations, indicating that treatment of the grafts with this drug may have adversely affected cells responsible for hematologic recovery.

Ex vivo purging allows the use of agents that are too toxic to nonhematopoietic tissue or are otherwise unsuitable for in vivo administration. Since toxicity to normal human hematopoietic stem cells can be expected with the various manipulations required for tumor cell purging and graft preservation, an indicator of the bone marrow repopulating potential of such treated cells would greatly enhance our ability to evaluate clinical autologous BMT regimens.

In this report we describe the in vitro assay of CFU-GM-derived colonies from 4-HC-treated bone marrow grafts in a series of patients undergoing autologous BMT at this center. The time to hematologic reconstitution (determined by the return of peripheral blood granulocytes, reticulocytes, and platelets) showed a linear correlation to the logarithm of CFU-GM content of the treated bone marrow grafts.

METHODS

Patient selection and transplant procedures. Hematopoietic progenitor cell assays were performed on the bone marrow grafts of 40 consecutive patients undergoing autologous BMT with 4-HC-purged bone marrows at this center. Eighteen of the patients were transplanted for the diagnosis of acute nonlymphoblastic leukemia in second remission and 16 for the diagnosis of refractory Hodgkin's disease (9) or non-Hodgkin's lymphoma (7). Five patients with pediatric solid tumors and one patient with acute lymphoblastic leukemia in first remission were also harvested. The age range for these patients was 2 to 53 years with a median of 29 years. Twenty-eight of the patients were male. The details of the induction regimens used have been previously reported.^{9,10} Patients with acute nonlymphocytic leukemia, Hodgkin's or non-Hodgkin's lymphoma with bulky disease, and pediatric solid tumors (neuroblastoma, melanoblastoma, and rhabdomyosarcoma) received busulfan (4 mg/kg daily $\times$ 4) and cyclophosphamide (50 mg/kg daily $\times$ 4) for induction. The remaining patients received an induction regimen consisting of cyclophosphamide (as noted above) and total body irradiation (TBI; to 1200 rad). All patients received appropriate supportive care, including prophylactic platelet transfusions for platelet counts less than 20,000/ μL . Approval for the therapeutic

application of autologous BMT at this center was obtained from the Joint Committee on Clinical Investigation of the Johns Hopkins Hospital and the Johns Hopkins University, and informed consent was obtained for all patients prior to bone marrow harvesting.

Marrow processing. The bone marrow grafts were collected, treated with 4-HC, cryopreserved, and thawed as previously described.^{7,8} Briefly, all bone marrows were incubated with 100 $\mu\text{g}/\text{mL}$ of 4-HC at a nucleated cell concentration of 2×10^7 cells/mL for 30 minutes at 37°C. The red cell contents of the incubation mixtures were not adjusted (the range of packed red cell volumes was 5% to 23% for this series). The cells were then resuspended for cryopreservation with 10% dimethyl sulfoxide (DMSO) in the liquid phase of nitrogen. Subsequently the cells were rapidly thawed in a 37°C water bath and immediately infused without further manipulation.

Cell culture. Aliquots of bone marrow cells were obtained from the bone marrow graft buffy coats before and after the 4-HC treatment (prior to the addition of cryoprotectants). Light-density mononuclear cells (sp gr ≤ 1.077 g/mL) from both the treated and untreated specimens were obtained by Ficoll-Hypaque (FH) separation. The cells were cultured in 1.32% methylcellulose containing alpha-medium (Gibco, Grand Island, NY), 5% phytohemagglutinin (PHA)-stimulated leukocyte-conditioned medium,¹¹ 1% bovine serum albumin (Sigma Chemical Co, St Louis), 30% fetal bovine serum (FBS, Hyclone, Logan, UT), 10^{-6} mol/L methylprednisolone, 10^{-4} mol/L 2-mercaptoethanol, and 1 U/mL erythropoietin (Amgen, Thousand Oaks, CA). Untreated cells were plated at a seeding density of 5×10^4 cells per 1-mL plate (Lux; Miles Laboratories, Naperville, IL). Treated cells were plated at multiple seeding densities from 5×10^4 to 1×10^6 cells/mL. All samples were cultured in quadruplicate and maintained at 37°C in a humidified 5% CO_2 in air atmosphere. CFU-GM-, BFU-E-, and CFU-GEMM-derived colonies were scored on an inverted microscope after 14 days of culture. The same bone marrow samples were also cultured for CFU-C as previously described.⁷ Briefly, 1×10^5 untreated, and 5×10^5 and 1×10^6 treated light-density cells were cultured in 1 mL of McCoy's medium (Gibco) containing 0.3% agar (Difco Laboratories, Detroit), 15% fetal bovine serum (FBS), and 10% human placenta-conditioned medium. Quadruplicate cultures were maintained at 37°C in a humidified 7.5% CO_2 in air atmosphere, and colonies containing >50 cells were enumerated on an inverted microscope after ten days.

Determination of bone marrow graft-progenitor cell content. The hematopoietic progenitor contents of the marrow grafts before and after incubation with 4-HC were determined by multiplying the number of colonies scored per number of cells seeded into culture by the number of nucleated cells (per kg recipient weight) within the grafts. Because the cloning efficiency of the treated cells fell to 80% of predicted at a seeding density of 10^6 cells/mL, all calculations of graft progenitor cell content were based, when possible, on the lowest seeding density giving rise to at least five colonies per plate (usually 5×10^5 cells/mL seeding density). We assumed that all progenitor cells were contained within the light-density fraction after density-gradient separation and multiplied the above product by the proportion of cells recovered within this fraction. $\text{CFU}/\text{kg} = \text{CFU}/\text{plate} \div \text{cells}/\text{plate} \times \text{cells}/\text{kg} \times \text{gradient recovery}$.

Analysis of hematologic recovery. Daily peripheral blood leukocyte counts were obtained following the reinfusion of the thawed bone marrows (day 0). When the WBC was less than $1,000/\mu\text{L}$, the WBC and granulocyte count were determined with flow cytometry (Spectrum III, Ortho Diagnostic Systems Inc, Westwood, MA). Above a WBC of $1,000/\mu\text{L}$, the WBC was determined on an automated cell counter (ELT 800, Ortho Diagnostic Systems Inc), and the granulocyte fraction was determined visually with Wright-stained peripheral blood smears. Platelet counts were determined

daily using the automated cell counter. Reticulocyte counts were measured twice weekly with the flow cytometer using acridine orange-stained specimens. The day of recovery is the first day after the reinfusion of the marrow on which the particular peripheral blood count (sustained leukocytes $\geq 1,000/\mu\text{L}$, granulocytes $\geq 500/\mu\text{L}$, reticulocytes $\geq 2\%$) is achieved. For analysis of platelet recovery we chose the time to the last platelet transfusion, which corresponded to a self-sustained peripheral blood platelet count of greater than $20,000/\mu\text{L}$ for most patients.

Statistical evaluation. The relation of the logarithm of the progenitor cell content of the bone marrow graft to the time of hematologic recovery of the recipients was evaluated by linear regression analysis and calculation of Pearson's correlation coefficient. The significance of the correlation parameters was tested by Student's *t* test.

RESULTS

The hematopoietic culture data for the various progenitor cells before and after incubation with 4-HC are shown in Table 1. The mean recovery of each progenitor cell type was similar (approximately 5%; 2% for CFU-C). However, CFU-GM-derived colonies were obtained from all bone marrows following the ex vivo incubation. BFU-E- and CFU-GEMM-derived colonies were grown from all specimens before treatment but from only 44% and 33% respectively of the specimens after treatment. CFU-C-derived colonies were cultured from only 17 (42%) of the treated bone marrow grafts.

The clinical protocols prescribed a minimum number of nucleated cells to be harvested and cryopreserved for the patients undergoing autologous BMT; therefore most patients had similar numbers of nucleated cells and CFU-GM within the bone marrow grafts prior to the purging steps. The mean CFU-GM content of the bone marrow grafts before the 4-HC incubation was $1.4 \pm 0.7 \times 10^5$ ($\pm\text{SD}$) per kg body weight (range, 0.5×10^5 to 4.0×10^5). The mean CFU-GM content after the 4-HC incubation was $7.6 \pm 13.3 \times 10^3$ ($\pm\text{SD}$) per kg with a range from 5.0×10^1 to 5.7×10^4 per kg. The recovery of CFU-GM within the graft after incubation with 4-HC ranged from 0.07% to 23%.

No relation was evident between the nucleated cell, CFU-C, BFU-E, or CFU-GEMM content of the treated bone marrow grafts and time to recovery of peripheral blood cells. The logarithm of the CFU-GM content showed a linear correlation with time to leukocytes $\geq 1,000/\mu\text{L}$, granulocytes $\geq 500/\mu\text{L}$, reticulocytes $\geq 2\%$, and time to last platelet transfusion (Figs 1 A to D). The logarithm of CFU-GM content also predicted the day of recovery when analyzed for subgroups of patients. This included the time to a WBC $\geq 1,000/\mu\text{L}$ for both the acute nonlymphocytic leukemia (ANLL) ($r = -0.79$, $n = 15$) and all lymphoma patients (Hodgkin's and non-Hodgkin's lymphomas, $r = -0.74$, $n = 11$), and time to 500 granulocytes/ μL ($r = -0.78$ and $r = -0.63$ respectively). Sufficient evaluable patient courses are not available for similar comparative analysis of time to recovery of platelets and reticulocytes. However, these data suggest that the relationship of CFU-GM to pluripotent stem cell contents of the bone marrow grafts after purging is similar for these patient groups and that the patient diagnoses do not affect the subsequent transplant course when the grafts are purged ex vivo with 4-HC. Only four patients with lym-

Fig 1. Number of days following bone marrow reinfusion to achieve: (A) peripheral blood total leukocyte count greater than 1,000/ μL , (B) peripheral blood granulocyte count greater than 500/ μL , (C) last platelet transfusion, and (D) peripheral blood reticulocyte concentration of greater than 2%. Correlation coefficients and the linear regression equation are shown for each curve. All slopes are significantly different from 0, as shown by the *P* values for each equation.

phoma for whom reconstitution data are available received induction with cyclophosphamide and total body irradiation (TBI), so a comparison within this particular diagnostic category for the two preparative regimens used cannot be made at this time.

Patients who could not be evaluated for reconstitution were lost to follow-up for a variety of reasons. Seven died before reaching 1,000 WBC/ μL , one patient relapsed, and one each were either not transplanted or received a "reserve" marrow (prior to time of predicted recovery) treated at a lower concentration of 4-HC. Similarly, 14 patients died while still receiving platelet transfusions, three patients relapsed, and two developed autoimmune thrombocytopenia.¹² Two of the patients who died while still requiring platelet support developed veno-occlusive disease of the liver,¹³ and one patient developed cytomegalovirus (CMV)-associated bone marrow failure¹⁴ prior to the predicted day of platelet recovery determined from the regression equation (Fig 1C). The remainder of the patients who died before white cell or platelet recovery expired prior to the day of predicted recovery. Two patients relapsed with leukemia while still receiving platelet support 83 and 116 days after the predicted day of recovery. No other factor for this delay in platelet recovery was obvious, and none of the lymphoma patients who relapsed had delayed platelet or white cell recovery.

DISCUSSION

Ex vivo manipulation of bone marrow grafts can affect the ability of these grafts to reconstitute the hematopoietic system of the recipients. In the phase I trial of purging

autologous bone marrows with 4-HC reported from this center,⁷ the time to hematopoietic recovery was related to the concentration of 4-HC to which the bone marrow grafts were exposed. Therefore an assay that demonstrates a strong correlation with the ability of the bone marrow graft to repopulate the hematopoietic system of the recipient is valuable both in terms of patient management as well as in the development or modification of purging techniques.

Other investigators have reported that the granulocyte-macrophage progenitor cell (CFU-GM) content of the autologous bone marrow graft relates either in a logarithmic fashion¹⁵ or in a step fashion² to the time to return of peripheral blood leukocytes but not platelets or reticulocytes after autologous BMT. These studies involved bone marrow grafts that were not exposed ex vivo to purging agents that could be toxic to normal committed and pluripotent progenitor cells or hematopoietic regulatory cells. In allogeneic transplantation a correlation between the CFU-GM content of the graft and hematologic reconstitution has^{16,17} and has not^{18,19} been reported. Common features of those studies that do not find a correlation are both a limited range in the number of progenitor cells infused and a usual dose of CFU-GM greater than $10^5/\text{kg}$ of recipient weight. Because our data support a model of exponential growth²⁰ of the infused bone marrow, the effects of minor (even twofold) variations in the number of CFU-GM infused may not be discernible in clinical studies. Thus patient-to-patient differences in cell loss during freezing or in the assumed FH recovery²¹ upon which our calculations are based may have little effect upon the overall correlation of progenitor cell content with hematologic reconstitution. The discrepancy

Table 1. Progenitor Cell Growth From Patient Bone Marrow

	Progenitor Cell			
	BFU-E	CFU-GM	CFU-GEMM	CFU-C
Untreated	46.7 ± 4.5*	63.0 ± 5.2	2.3 ± 0.3	15.9 ± 2.2
4-HC-treated	0.3 ± 0.1	3.0 ± 1.0	0.06 ± 0.02	0.06 ± 0.02

*Mean ± SEM. Shown are the number of colonies per 5×10^4 cells for both the treated and untreated bone marrow samples. N = 40.

between our current data and the lack of correlation of CFU-C (CFU-GM) with hematologic reconstitution previously reported from this center⁷ results from the different progenitor cell assays used. The culture conditions described in this report have a lower threshold for detection of progenitor cells following the 4-HC incubation (Table 1), and cultures of the grafts in this series using the previously reported assay techniques again demonstrated almost complete abrogation of clonal growth at this concentration of 4-HC. The two assay techniques differ greatly, and we cannot attribute the better growth in our current assay to any particular reagent(s). Because a threshold of detection also exists for the current assay, failure to grow only implies that the period of aplasia may be prolonged.

Many factors can affect the recovery of CFU-GM for bone marrow grafts manipulated ex vivo including incubation with 4-HC (as shown in this study) or other purging agents.^{22,23} Presumably the decreases in measurable (by in vitro culture) CFU-GM reflect a similar effect upon the primitive hematopoietic stem cell responsible for reconstitution following bone marrow transplantation. Other purging regimens, especially those that use monoclonal antibodies (MoAbs), which theoretically have the potential of distinguishing between committed and pluripotent progenitor cells, may dissociate the close relationship of CFU-GM to the hematopoietic stem cell implied by our results. The development of pluripotent stem cell assays^{11,24-27} may simplify the investigation of this aspect of BMT.

Although it is conceivable that the granulocyte colonies we observed arose from pluripotent stem cells, we would in this circumstance have expected to identify other colony types (erythroid, mixed granulo-erythroid) in the culture dishes as well. The stronger correlation of graft CFU-GM content to granulocyte rather than platelet or reticulocyte recovery may reflect the lineage commitment of this progenitor cell. How-

ever, other factors may have contributed to the relatively weaker correlation of the CFU-GM content with platelet and reticulocyte recovery. We routinely transfused platelets prophylactically for platelet counts below 20,000/ μ L, and for medical complications such as severe liver disease,¹³ CMV infection,¹⁴ and immune destruction,¹² may affect platelet survival or production. Similar considerations may affect the recovery of red cell production in these patients. In this series three patients died while still requiring platelet support after platelet recovery was predicted, but all had developed complications of transplantation prior to expected platelet recovery. Two patients who relapsed with acute myelogenous leukemia had prolonged platelet requirements without other explanation. The linear relationship of CFU-GM content to hematologic recovery and the occasional prolonged aplasias observed in this group of patients suggest that the preparative regimens employed are marrow-ablative and that spontaneous recovery is not responsible for the hematopoietic reconstitution of these patients.

These data confirm that the in vitro quantitation of CFU-GM can correlate with engraftment following autologous BMT with manipulated bone marrow grafts. Although other purging regimens may not demonstrate the same relationship, attention should be given to in vitro models of engraftment. The development of assays for more primitive pluripotent hematopoietic stem cells may simplify this task.

ACKNOWLEDGMENT

We wish to thank Catherine Hattenburg and Barbara Hooke for their laboratory expertise in the progenitor cell cultures for this study and Cassandra Yelverton for her secretarial assistance in the preparation of this manuscript. We also wish to thank the many physicians, physician assistants, nurses, and support staff of the Johns Hopkins Oncology Center involved in the care of these patients.

Immunologic Aberrations, HIV Seropositivity and Seroconversion Rates in Patients With Hemophilia B

By Doreen B. Brettler, Frank Brewster, Peter H. Levine, Ann Forsberg, Sharon Baker, and John L. Sullivan

Because there have been reports that factor IX concentrate is less immunosuppressive and therefore factor IX users have less immunologic aberrations, we have studied a group of 22 patients with hemophilia B and six patients with factor VIII deficiency and high titer inhibitors with respect to lymphocyte numbers and function, human immunodeficiency virus (HIV) serology, and factor usage. This group was compared to 111 patients with hemophilia A and a group of 28 healthy male volunteer controls. When the study began in 1983, the majority of patients with hemophilia B and with higher titer factor VIII inhibitors were seronegative, 77% and 83% respectively, as compared to only 30% of patients with hemophilia A. At that time the factor IX users also had milder immune aberra-

tions than the hemophilia A group. However, with time and increasing clotting factor concentrate usage, seroconversion and more striking abnormalities in immune function have occurred in the hemophilia B group. In a subgroup of 16 patients with hemophilia B studied twice, the incidence of seropositivity increased from 31% in 1983 to 69% in 1985. We thus conclude that factor IX concentrate in itself is not less immunosuppressive than factor VIII concentrate. Seroconversion in factor IX concentrate users appears to be lagging behind seroconversion in factor VIII concentrate users, perhaps secondary to the lower cumulative dosage of concentrate that patients with hemophilia B utilize.

THERE HAVE BEEN numerous reports of laboratory immune abnormalities, including reduced helper/suppressor lymphocyte ratios, anergy to cutaneously applied antigens, and decreased mitogen responsiveness in patients with factor VIII deficiency (hemophilia A).¹⁻⁴ The cause of these abnormalities is multifactorial, with the most important variables being the amount of factor concentrate infused and seropositivity to HIV (human immunodeficiency virus).⁴ Beginning in 1983 there have been suggestions in the literature that those patients with factor IX deficiency (hemophilia B) as well as those with high titer inhibitors to factor VIII receiving large amounts of factor IX concentrate have a lesser degree of immune dysfunction than patients with hemophilia A.⁵⁻⁹ However, in each of these studies the sample size was small, and correlations between seropositivity to HIV and immune data were not always available. In these studies it was implied that the factor IX concentrate was in itself less immunosuppressive. However, other reports suggested that immune aberrations were dependent on intensity of treatment. In one study, for example, patients who were intensively treated with factor IX concentrates were found to have decreased helper/suppressor cell ratios when compared to patients with hemophilia B who used minimal amounts of clotting factor concentrates.¹⁰

Patients with hemophilia B characteristically infuse fewer units per year than patients with hemophilia A. It remains

unclear, therefore, whether factor IX concentrate is less immunosuppressive than factor VIII concentrate or if the degree of immune aberration is directly related to the amount of total units infused. We have studied a group of patients with factor IX deficiency and also a group of factor IX concentrate recipients with high titer inhibitors to factor VIII with respect to lymphocyte number and function, HIV seropositivity, and factor usage. Additionally, to test the hypothesis that factor IX-deficient patients are lagging behind in HIV seroconversion and the development of immune defects because of lower cumulative factor doses, we restudied the HIV seroconverters again after two to three years for progressive alterations in immunoregulation.

MATERIALS AND METHODS

Patient selection. Twenty-two patients with hemophilia B who were enrolled at the New England Area Comprehensive Hemophilia Center were consecutively tested at the time of their routine annual visit. All were tested at least once in 1983/1984, and 16 were tested subsequently after a two-to-three-year period from 1983 to 1985. Fourteen patients had severe hemophilia B (factor level <1%), one patient had severe hemophilia B with a high titer inhibitor, and six had moderate hemophilia B (factor IX = 2% to 5%). A final patient had severe hemophilia B by laboratory measurement but was mild clinically and never had infused any blood products. All patients were on a home therapy program as described previously,¹¹ utilizing commercial factor IX concentrate from a variety of manufacturers except for the one patient who never infused concentrate and had last been infused with plasma approximately 30 years ago. All patients began to use heat-treated factor IX in January 1985. None of the 22 patients had acquired immune deficiency syndrome (AIDS) or AIDS related complex (ARC). Six of the 22 patients were noted to have small but palpable lymph nodes in the anterior and posterior cervical node chains. One patient had a six-week episode of weight loss and fevers that have subsequently resolved. In retrospect, this particular episode was most likely related to seroconversion to HIV positivity. The mean age of the group with hemophilia B was 25.7 years, with a range of 5 to 60 years.

Additionally, six patients with severe hemophilia A and high titer inhibitors, five of whom had received only factor IX products over the last five years and one who had received factor VIII concentrate in addition to factor IX concentrates, were studied. Their inhibitor titers ranged from 3.3 to 11.5 Bethesda Units. These patients ranged in age from 6 to 37 years, with a mean of 19 years. No patient in this

group had AIDS, ARC, lymphadenopathy, or thrombocytopenia. A group of 111 patients with hemophilia A that had been previously completely characterized with respect to immune function and HIV serology served as a comparison group.⁴ The nonhemophilic control group consisted of 28 healthy male volunteers on no medications who had a mean age of 33.5 years, with a range of 18 to 54 years. The characteristics of these groups are seen in Table 1.

Lymphocyte separation. Peripheral blood mononuclear cells (PBMC) were isolated from freshly drawn heparinized venous blood by centrifugation on Ficoll-Hypaque (FH; Pharmacia Fine Chemicals, Inc, Piscataway, NJ) density gradients. PBMC preparations contained 70% to 80% lymphocytes, 10% to 20% monocytes, and 20% polymorphonuclear leukocytes as determined by cell morphology. All studies were performed on PBMC maintained at 37°C overnight in HEPES-buffered RPMI 1640 medium (Grand Island Biological Co, Grand Island, NY) supplemented with 10% fetal calf serum (FCS), and 25 µg/mL gentamicin (Grand Island Biological Co, Grand Island, NY).

Lymphocyte surface marker studies. Relative percentages of T lymphocyte populations were enumerated using indirect immunofluorescence and the following reagents: mouse monoclonal antibodies (MoAbs) OKT.11 (pan-T cell), OKT.4 (T helper/inducer) and OKT.8 (cytotoxic/suppressor; Ortho Pharmaceutical Co, Raritan, NJ). HLA-DR-bearing lymphocytes were enumerated using direct immunofluorescence with a fluorescein-conjugated mouse MoAb to a common determinant of human HLA-DR from Becton Dickinson Company (Mountain View, CA). All samples were analyzed with the use of a Becton Dickinson FACS IV. Absolute numbers of the various cell population per microliter of whole blood were calculated by multiplying their relative percentage by the absolute numbers of

peripheral blood mononuclear cells as determined from complete blood counts.

Lymphocyte proliferation studies. Using a standard microculture method,¹² 5×10^4 PBMC in 0.25 mL of RPMI 1640 with 10% fetal calf serum (FCS) were distributed into replicate wells of Microtiter II plates (Falcon Labware, Division of Becton Dickinson and Co, Oxnard, CA). Mitogens were added in the following concentrations: phytohemagglutinin (PHA; Burroughs Wellcome, Research Triangle Park, NC) 0.2 to 8.0 µg/mL; pokeweed mitogen (PWM; PL Biochemicals, St. Louis) 0.05 to 5 µg/mL; concanavalin A (Con A; Calbiochem-Behring Corp, American Hoechst Corp, San Diego, CA) 0.4 to 40 µg/mL. Cultures were terminated on day 3 for PHA, day 5 for Con A and PWM. All cells were cultured in a 5% CO₂ environment at 37°C. Eighteen hours before harvesting, the cultures were pulsed with 2 µCi of ³H-thymidine, (³HTdR; sp act 6.7 mCi/mmol/L; New England Nuclear, Boston). Cells were harvested onto glass-fiber filters, and ³H-thymidine content was determined by scintillation counting. All cultures were performed in triplicate.

Delayed cutaneous hypersensitivity. Delayed cutaneous hypersensitivity (DCH) was measured in both hemophiliacs and controls using the Multitest CMI (Merieux Institute Inc, Miami) skin test set.¹³ Seven test recall antigens (tetanus toxoid, diphtheria toxoid, streptococcus, proteus, tuberculin, candida, and trichophyton) and a glycerine-vehicle control were simultaneously applied on the volar surface of the arm with the multipuncture set. The skin tests were read at 48 hours, and the presence of induration of greater than 2 mm for each antigen was recorded. A patient was considered anergic if no skin tests were positive after 48 hours and a responder if one or more skin tests were positive.

HIV serology. Serum samples were assayed for IgG antibody to HIV using a modification of an indirect immunofluorescent assay described previously.¹⁴ Patient sera were also analyzed for antibody to HIV viral proteins by the Western blot method.¹⁵ Briefly, sodium dodecyl sulfate (SDS)-disrupted HIV (kindly provided by R.C. Gallo) was fractionated on a discontinuous polyacrylamide-SDS gel system and then electrophoretically transferred to a sheet of nitrocellulose (Schleicher and Schuell, Keene, NH) by methods described previously.¹⁶ After blocking with 5% nonfat dry milk saline solution, the Western blot was then cut into strips and reacted with a 1:100 dilution of patient serum overnight at room temperature. The strips were first reacted with biotinylated goat antihuman IgG and then avidin D-conjugated horseradish peroxidase (Vector Labs, Burlingame, CA). A 4-chloro-1-naphthol substrate solution was added for ten minutes, then the color reaction was stopped and the banding pattern compared to patterns obtained with HIV positive sera, with

special note made of antibody reactivity to p24 (viral core antigen) and gp41 (envelope glycoprotein).

Statistical analysis. Statistical differences between groups were evaluated by the use of Student's *t* test.

RESULTS

Surface markers. As can be seen in Table 2, patients with hemophilia B had significantly decreased percentages of T helper cells ($36.7 \pm 7.9\%$ v $48.1 \pm 8.3\%$, $P < 0.005$) when compared to the nonhemophilic control group. The absolute number and the percentages of suppressor cells were increased and the helper/suppressor ratio significantly decreased when compared to controls. When compared to the group with hemophilia A, however, absolute number and percentage of helper cells were increased, and relative amounts of suppressor cells were significantly decreased, making the helper/suppressor ratio higher and more similar to the normal controls. Percentages of HLA-DR cells were also not significantly different from the control population. The six patients with factor VIII deficiency and high titer inhibitors, although utilizing large amounts of factor IX, had in vitro immunologic tests that were not significantly different from the normal controls.

Mitogens. The responses to the mitogens PHA, Con A, and PWM were all significantly decreased in the patients with hemophilia B when compared to controls, as can be seen in Table 3. The responses were similar to those patients with hemophilia A.

Delayed cutaneous hypersensitivity. As we have reported previously,¹⁷ no patient with hemophilia B was anergic, as compared to 51% of patients with hemophilia A. Of the 17 patients on whom results were available, all had at least one skin test that was positive. The mean number of tests that were positive for hemophilia B patients was 2.5 ± 1.2 as compared to 1.2 ± 0.1 for hemophilia A patients and 3.5 ± 1.5 for controls (data not shown).

Factor concentrate usage. The group of patients with hemophilia B used significantly less clotting factor concentrate than those with factor VIII deficiency (757 ± 910 units factor IX/kg/yr v 1384 ± 252 units factor VIII/kg/yr, $P < 0.005$). Interestingly, those with inhibitors to factor VIII, although normal from an immunologic standpoint, used significantly increased amounts of factor concentrate when compared to both those with factor IX deficiency (5315 ± 3436 units factor IX/kg/yr v 758 ± 909 units factor IX/kg/yr, $P < 0.005$) and those with factor VIII deficiency (5315 ± 3435 units factor IX/kg/yr v 1384 ± 1252 units factor VIII/kg/yr, $P < 0.005$).

HIV serology. When comparing serology among the different groups, it is notable that in 1983, the first year that the patients were studied, 17/22 or 77% of patients with hemophilia B were seronegative as well as 5/6 patients with inhibitors to factor VIII. This is compared to only 30% of patients with factor VIII deficiency who were initially seronegative. The five patients with hemophilia B who were initially seropositive did use significantly higher amounts of factor IX concentrate than those with hemophilia B who were seronegative (Table 4). Thus it appears that in the hemophilia B population, increased amounts of clotting factor concentrate usage increases the incidence of seropositivity. In contrast to what has been reported in the group with hemophilia A,⁴ seropositivity to HIV in the group with hemophilia B studied in 1983 did not correlate with either decreased responsiveness to PWM or an increased amount of circulating HLA-DR-positive lymphocytes (Table 4).

In the patients with inhibitors to factor VIII who use large amounts of factor IX, the initial seropositivity rate was only 1/6 or 16.6%. It remains unclear why the patients who utilized the most factor IX, the inhibitor patients, had an initial low rate of seropositivity; this may only be a reflection of the small sample size for this group.

Longitudinal studies. Sixteen patients with hemophilia B were studied in year 1 (1983) and then in a subsequent

Table 4. Variables Correlating With HIV Seropositivity in 1983

	Hemophilia A: HIV Serology		Hemophilia B: HIV Serology	
	Negative (n = 28)	Positive (n = 83)	Negative (n = 17)	Positive (n = 5)

† $P < 0.005$ when compared to seronegative counterpart.

year, year 2 (1984 and/or 1985) with respect to immune function and HIV serology. In this subgroup of patients the number of those who were seropositive increased from 5/16 (31%) in 1983 to 11/16 (69%) in 1985. There were six seroconverters during that time period. When these six patients were compared with respect to immunologic parameters between year 1 and year 2, there was a decrease in T helper/suppressor ratio from 1.65 ± 0.95 to 1.15 ± 0.50 , which did not reach significance (Fig 1), and a trend toward a decrease in absolute T helper cells and an increase in absolute T suppressor cells (Fig 2). One patient who seroconverted did have an acute but prolonged febrile illness in retrospect associated with seroconversion. Otherwise the group of seroconverters did not differ clinically from the group as a whole.

The five patients who remained seronegative actually had an increase in the helper/suppressor cell ratio from 1.28 ± 0.69 to 1.46 ± 0.76 secondary to a slight increase in helper cells (data not shown). They also used clotting factor concentrates from a variety of manufacturers and did not differ clinically from the patients who seroconverted. Interestingly, it is of note that the utilization of factor concentrate over the study period 1983 to 1985 was not significantly different between the patients who seroconverted and the patients who remained seronegative (330 ± 323 units/kg/yr v 706 ± 497 μ /kg, P is not significant). However, these subsets represent very small patient groups, and thus statistical comparison is difficult.

The five patients who were initially seropositive remained the same immunologically with decreased helper/suppressor ratios secondary to both decreased helper cells and increased suppressor cells. It should be noted that the intensity of treatment had not changed in these patients during the interval between the two sets of studies.

The six patients with inhibitors were also studied longitudinally. Three patients seroconverted. The mean helper/suppressor cell ratio of the six patients at the outset of the study was 1.70 ± 0.96 , whereas in 1985, after the three seroconversions occurred, the mean ratio was 0.77 ± 0.26 , a significant downward trend ($P < 0.025$).

DISCUSSION

In numerous reports, patients with hemophilia B have been shown to have less immunologic aberrations than

Fig 1. Decrease in the T helper cell/T suppressor cell ratio in the patients with hemophilia B who seroconverted during the study period. I represents the first year of study and II the subsequent study year. The difference in the mean ratio between the two groups is not significant. Each dot represents an individual patient.

Fig 2. Absolute numbers of T helper cells and T suppressor cells studied in the seroconverters over time. I represents the first year of study when patients were seronegative and II the subsequent study year when they had seroconverted. The trend shows a decrease in the mean absolute T helper cells and an increase in mean absolute T suppressor, but the differences are not statistically significant.

patients with factor VIII deficiency. It has been found that the factor IX concentrates have decreased amounts of beta-2 microglobulin protein when compared to factor VIII concentrates. This has been postulated as a reason why these concentrates might cause less immunosuppression than do factor VIII concentrates.⁸ Recently it has been reported that a prolonged exposure to ethanol during plasma fractionation can inactivate HIV virus.¹⁸ Since certain factor IX products, especially activated prothrombin complex used intermittently by patients with inhibitors, are made utilizing such a step, less immune aberrations have been postulated to occur in patients using these products. In one study, patients treated only with activated prothrombin complex were shown to have no seroconversion over a three-year period.¹⁹ Another reason put forth that patients with hemophilia B may have more normal immune function is that a smaller percentage of patients with hemophilia B are HIV antibody positive. In Great Britain only 6.3% of 316 hemophilia B patients studied were seropositive.²⁰

In our group of 22 patients with hemophilia B and six patients with inhibitor to factor VIII studied initially in 1983, immunologic abnormalities were less striking than in a comparison group of patients with hemophilia A and more similar to a normal control group. When compared to patients with hemophilia A, we found, as previously reported by others,^{6,9} that helper/suppressor ratios were higher as a result of increased amounts of helper cells and decreased numbers of suppressor cells. Skin test anergy was also absent in all patients with factor IX deficiency and also the inhibitor patients.

In 1983 the seropositivity rate in the patients with hemophilia A was 72%, in contrast to a rate of 31% in patients with hemophilia B and 16.6% in patients with high titer inhibitors. Seropositivity to HIV was correlated with higher clotting factor concentrate usage in the population with hemophilia B found to be seropositive at first testing. This finding is comparable to that of Mannucci et al²¹ as well as to data from other European and American hemophilia centers.^{22,23} Overall, the amount of factor infused was less than in the

population with factor VIII deficiency. Based on the above information, one could hypothesize that the factor IX itself is not less immunosuppressive but that less of it was used per patient. Seropositivity and subsequent immunologic aberrations should emerge later, in time, as either the cumulative dose increases or the probability of exposure to an HIV-contaminated lot increases.

Supporting this hypothesis is the data on the 16 patients with hemophilia B who were studied over at least two consecutive years. There was a 38% seroconversion rate, with 6/16 becoming seropositive. Correlated with seroconversion was a trend toward worsening of immune function. The incidence of seropositivity in the hemophilia B population may never reach that in patients with hemophilia A, since future seroconversion may well be prevented by the newer heat-treated concentrates that will likely eliminate further HIV exposure.

Thus it appears that factor IX concentrate itself is not less immunosuppressive but that less per year has been utilized in the hemophilia B patients when compared to factor VIII usage in hemophilia A patients. The correlation between amount of factor infused, conversion to HIV antibody positivity, and subsequent immunologic aberrations when examined in 1983 is similar to that seen in patients with factor

VIII deficiency, only delayed. It is of note that the patients who seroconverted during the study years did not use more factor concentrate over the three-year span than those who continued to remain HIV antibody negative. Thus not only cumulative dose but chance exposure to a HIV-contaminated lot could also be important. These results also suggest that a more purified factor IX preparation is needed to decrease the immunosuppression observed in patients with hemophilia B receiving concentrate infusions.

The data concerning the factor VIII inhibitor patients are difficult to interpret, since the group represents a small subset. Because the patients appeared at the outset of the study to have normal immune studies, they may have been, in some manner, protected from the immune suppressant effects of large doses of factor IX concentrate. However, over the course of two years, 3/6 patients with inhibitors seroconverted, and their immune function deteriorated. This is consistent with the immunologic deterioration seen in patients with hemophilia A or B following HIV infection.

ADDENDUM

Since this paper was originally submitted, 21 of the 22 original patients with hemophilia B have seroconverted as well as five of the six inhibitor patients.

Plasma and Platelet HLA in Normal Individuals: Quantitation by Competitive Enzyme-Linked Immunoassay

By K. J. Kao

Recent studies on platelet HLA indicate that >50% of platelet HLA antigens are adsorbed on the platelet surface and may be derived from plasma. It has been speculated that platelet HLA may be directly proportional to plasma HLA concentration. To determine the quantitative correlation between plasma and platelet HLA, a precise competitive enzyme-linked immunoassay (ELISA) for measurements of soluble and cellular HLA antigens was developed by using purified HLA antigens and W6/32 anti-HLA monoclonal antibody. The useful range of the standard curve for the assay was 0.01 to 5.0 $\mu\text{g/mL}$. The intraassay and interassay variations were 7% and 14%, respectively. The plasma HLA concentrations measured in 61 healthy adults ranged from 0.25 to 4.1 $\mu\text{g/mL}$, and the mean plasma HLA concentration was $1.47 \pm 0.87 \mu\text{g/mL}$ ($\pm\text{SD}$). Platelet HLA concentrations determined in the same 61 persons ranged

from 4.7 to 17.33 fg/platelet, and the mean concentration was $9.3 \pm 2.9 \text{ fg/platelet}$ ($\pm\text{SD}$). Chloroquine-elutable platelet HLA concentrations were also determined in 42 of the 61 persons, with the mean value of $5.7 \pm 2.1 \text{ fg/platelet}$ ($\pm\text{SD}$). The plasma HLA concentration of each individual was then correlated with the same person's total or chloroquine-elutable platelet HLA concentration. Linear regression analyses of the results revealed no significant correlation between platelet and plasma HLA concentrations. Thus, it is unlikely that chloroquine-elutable HLAs are derived from plasma. The developed solid-phase assay for HLA will be useful for further study of the quantitative significance of plasma HLA antigens in allosensitization of transfused individuals.

© 1987 by Grune & Stratton, Inc.

CLASS I MOLECULES of the human major histocompatibility complex (HLA) are the most important antigenic system in determining the survival of transfused platelets in alloimmunized recipients.¹⁻³ Recently, on the average of 50,000 to 120,000 molecules of HLA antigens per platelet were demonstrated to exist among different individuals,⁴ and >50% of platelet HLA antigens can be selectively removed by acid-hypertonic chloroquine without affecting platelet membrane integrity⁵ and other platelet membrane glycoproteins.^{5,6} The platelet-surface HLA antigens removed by chloroquine could also be detected in the eluate.^{4,5} These results suggest that most platelet HLA antigens are adsorbed on the platelet surface and do not span the platelet plasma membrane.

The existence of soluble HLA antigens in serum^{7,8} was first reported in 1970. Subsequent studies on a few individuals suggested that quantitative expression of HLA-B12 antigen on platelets was proportional to the serum content of that antigen.⁹ Later, Lalezari and Driscoll¹⁰ qualitatively demonstrated that platelets have the ability to acquire HLA specificity from plasma. These results suggest that adsorbed platelet HLA antigens may be derived from plasma and that platelet HLA antigens may be quantitatively proportional to plasma HLA antigens. In addition, Pellegrino and associates¹¹ reported that anti-HLA antibodies were elicited in individuals who had received intravenous (IV) infusion of

human plasma. Their finding indicates that plasma HLA is immunogenic. Nevertheless, concentrations of soluble plasma HLA antigen have only been measured semiquantitatively by inhibition of a lymphocytotoxicity test^{12,13} or by neutralization of a platelet cytotoxicity test.^{9,14}

We report the development of a competitive enzyme-linked immunoassay (ELISA) for precise quantitation of both plasma soluble and platelet cellular HLA antigens. The assay uses purified HLA antigens and W6/32 anti-HLA monoclonal antibody, and was applied to study the quantitative correlation between platelet and plasma HLA concentrations. The potential application of the assay to study plasma HLA immunogenicity is discussed.

MATERIALS AND METHODS

Isolation of W6/32 anti-HLA monoclonal antibody. The W6/32 hybridoma, obtained from the American Type Culture Collection (Rockville, MD), was originally developed by Barnstable, and co-workers¹⁵ and produces an IgG_{2b} monoclonal antibody that recognizes a common monomorphic determinant on HLA-A, B, and C molecules. W6/32 anti-HLA monoclonal antibody (W6/32 McAb) was isolated from culture medium by protein A-affinity column chromatography as described previously.⁴

Purification of HLA antigens. Sixty units of outdated platelet concentrates were obtained from the Civitan Regional Blood Center (Gainesville, FL). Platelets from each unit of platelet concentrate were washed twice with 50 mL of 0.02 mol/L of Tris-HCl, pH 7.4, containing 0.15 mol/L of NaCl and 2 mmol/L of EDTA (Tris-saline-EDTA). Washed platelets were pooled, centrifuged at 10,000 g for 10 minutes, and solubilized by resuspension in a equal volume of 2% NP-40 made in 0.02 mol/L of Tris-HCl, pH 7.4, containing 1 mmol/L of phenyl-methyl-sulfonyl fluoride (PMSF) and 1 mmol/L of ϵ -amino-*n*-caproic acid (EACA). The resuspended platelets were incubated on ice for 60 minutes. Solubilized platelets were then centrifuged at 10,000 g for 10 minutes at 4°C. The supernatant was collected and centrifuged again at 50,000 g for 60 minutes at 4°C. Solubilized HLA antigens were then isolated from the final supernatant by column chromatography on the following three sequentially linked columns: (a) a Sepharose-4B column, (b) a normal mouse IgG-Sepharose-4B column, and (c) a W6/32 McAb-Sepharose 4B column. Details of preparing the columns have been described previously.¹⁶ The size of each column was 1.6 $\times$ 6 cm. After

extensive washing, HLA antigens were eluted by 0.05 mol/L of diethylamine, pH 11.5, containing 0.1% NP-40 and collected in 1-mL fractions. The eluted protein peak was pooled and dialyzed extensively against 0.01 mol/L of phosphate-buffered saline (PBS), pH 7.2, containing 0.05% Na₂S₂O₅ and 0.1% NP-40. The concentration of HLA antigens was determined by a modified Lowry assay¹⁷ using bovine serum albumin (BSA) as the standard. Homogeneity of purified HLA antigens was evaluated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).¹⁸

Preparation of platelet samples for HLA assay. Platelets were isolated from freshly drawn venous blood by differential centrifugation and washed as described.⁴ Routinely, the venous blood was drawn into a 7-mL vacutainer containing EDTA as an anticoagulant. The washed platelets were suspended in 3 mL of Tris-saline-EDTA buffer and enumerated by a S-plus Coulter counter (Coulter Electronics, Hialeah, FL). The contamination of WBCs is always <0.01%. Ten to 40 million washed platelets were pipetted into a 1-mL conical polystyrene tube and pelleted by a Beckman Microfuge B (Beckman Instruments, Palo Alto, CA) at room temperature for 2 minutes. The supernatant was aspirated and discarded. Platelets were then resuspended in 100 μ L 0.02 mol/L of Tris-HCl, pH 7.4, containing 0.05% NP-40, 5 mmol/L of EDTA and 1 mmol/L of PMSF, and left on ice for 60 minutes with occasional vortexing. After solubilization, all samples were stored at -70°C until assayed. The frozen samples were stable for at least 12 months at -70°C. Chloroquine-treated platelets were prepared as reported previously.⁴

Competitive ELISA for HLA antigens. Each well of a 96-well Immunoplate (Nunc Inter-Med, Kamstrup, Denmark) was incubated overnight with 100 μ L of purified HLA antigens (2 μ g/mL) diluted in 0.01 mol/L of sodium phosphate buffer, pH 7.2, containing 0.15 mol/L of NaCl and 0.02% NaN₃ (PBS-azide) at 4°C. Subsequently, each well was washed three times with PBS-azide containing 0.5% Tween-20 (PBS-T) and then blocked with 300 μ L 1% BSA in PBS-T for 30 minutes at room temperature. After the wells were washed three times, 50 μ L of different concentrations of purified HLA standard (0.01 to 5 μ g/mL), diluted plasma or solubilized platelet samples were added to wells in duplicate, followed by the addition of 50 μ L W6/32 anti-HLA McAb (0.02 μ g/mL). The incubations were mixed by placing plates on a Micro-Shaker II (Dynatech Laboratories, Alexandria, VA) for 15 seconds, and incubated at room temperature for 90 minutes. The plate was washed three times again, followed by addition of 100 μ L of rabbit antimouse IgG alkaline phosphatase conjugate (1,000 $\times$ dilution) (Sigma Chemical, St Louis) into each well and incubated for 30 minutes.

Finally, 200 μ L *p*-nitrophenyl phosphate disodium (1 mg/mL prepared in 0.01 mol/L of sodium bicarbonate buffer, pH 9.6, containing 2 mmol/L of MgCl₂) was added to each well, and the plates were incubated at room temperature for 90 to 120 minutes in the dark. Fifty microliters of 3N NaOH was then added to each incubation to stop the reaction. Absorbance of each well at a wave length of 405 nm was measured in a BioRad ELISA plate reader (BioRad Laboratories Richmond, CA). All samples were diluted as needed in PBS-T containing 1% BSA and 5 mmol/L of EDTA and were assayed in duplicate. Plasma samples were also assayed at two different dilutions (5 $\times$ and 10 $\times$) to ensure absence of interfering factors.

RESULTS

Isolation of platelet HLA antigens. HLA antigens isolated from solubilized platelets appeared to be homogeneous as judged by SDS-PAGE (Fig 1). The purified HLA antigens consist of a 44-kd heavy chain and a 12-kd noncoval-

Fig 1. Sodiumdodecyl sulfate-polyacrylamide gel (12.5%) electrophoresis of purified HLA antigens. The purified HLA antigens consist of a 44-kd heavy chain and a 12-kd noncovalently associated β_2 -microglobulin. The same two polypeptide chains were also noted after reduction by 5% mercaptoethanol.

ently associated β_2 -microglobulin. Routinely, 2 to 3 mg of HLA antigens were recovered from 60 U of outdated platelet concentrates. These purified HLA antigens were used to coat the wells and served as standards for the assay.

Competitive ELISA for HLA antigens. The quantitative assay for HLA antigens was developed based on the principle of competition for the binding of W6/32 anti-HLA McAb between plate-bound HLA antigens and unbound HLA

Fig 2. Standard curve of the competitive enzyme-linked immunoassay for HLA antigens (—●—). (A) absorbance of each well at 405nm; (Ao) mean absorbance of duplicated wells in which no purified HLA antigen was added. Open circles represent 5 $\times$, 10 $\times$, and 20 $\times$ dilutions of pooled normal plasma (—○—); squares, same dilutions of HLA-depleted pooled plasma (—□—). Dilutions of 4×10^7 platelets solubilized in 100 μ L of lysing buffer (—△—).

antigens in the standards or unknown samples. The concentrations of the HLA antigens used to coat the wells ($2.0 \mu\text{g/mL}$) and W6/32 anti-HLA McAb ($0.02 \mu\text{g/mL}$) used in the assay were found to be optimal to gain greater sensitivity and precision. As shown in Fig 2, the useful range of the standard curve was between 0.01 and $5.0 \mu\text{g/mL}$.

When plasma pooled from six different healthy adults without history of previous blood transfusion or pregnancy was assayed at different dilutions, the values were in parallel with the standard curve (Fig 2). The result indicates that there was no factor(s) in plasma interfering with the assay. Next, the specificity of the assay was evaluated by assaying a HLA-depleted pooled plasma prepared by incubating pooled plasma with equal volumes of PA2.6 anti-HLA McAb-Sepharose 4B beads at 4°C for 4 hours. PA2.6 anti-HLA antibody was an IgG₁ monoclonal antibody developed by Brodsky and Parham.¹⁹ As expected, no significant amount of HLA could be measured in the sample after absorption (Fig 2).

Next, both plasma and serum samples were prepared from each of six different volunteer donors and assayed for HLA concentrations. No significant difference was observed between plasma and serum HLA concentrations ($P > .5$). The intraassay and the interassay assay variations were evaluated according to the method described by Bauer and Kennedy.²⁰ Pooled normal plasma was divided into aliquots and frozen at -70°C . On each of the ten different dates, one aliquot was thawed and assayed in duplicate. The intraassay and interassay variations were 7% and 14%, respectively.

Quantitation of platelet HLA concentrations. To measure cellular HLA concentration with the developed competitive ELISA, washed platelets (4×10^7 cells) were solubilized with 0.5% NP-40. The solubilized platelet sample was serially diluted and assayed. As shown in Fig 2, the results

were in parallel with the standard curve of the assay, which excluded presence of any interfering factor(s) in the solubilized platelet samples.

To determine whether the amount of detergent used was sufficient to solubilize platelets, 1×10^7 to 4×10^7 washed platelets from each of three different individuals were lysed by $100 \mu\text{L}$ of solubilization buffer and then assayed. If $100 \mu\text{L}$ of 0.5% NP-40 is capable of solubilizing all the platelets and releasing all cellular HLA antigens, a linear correlation should be expected between HLA contents and the number of platelets solubilized. As shown in Fig 3, the amount of HLA indeed was linearly proportional to the number of platelets solubilized. Thus, $100 \mu\text{L}$ of 0.5% NP-40 was sufficient to release HLA from $\leq 4 \times 10^7$ platelets.

The competitive ELISA was further evaluated by comparing this method with the surface binding assay in which ^{125}I -labeled W6/32 Fab fragments were used. Concentrations of platelet HLA of four different individuals were determined by these two separate methods. As shown in Table 1, platelet HLA concentrations determined by either method yielded similar results.

Quantitative correlation between plasma and platelet HLA concentrations. After validation of the assay, plasma and platelet samples were collected from 61 healthy volunteer donors and assayed for their HLA concentrations. The range of plasma HLA concentrations was from 0.25 to $4.1 \mu\text{g/mL}$, and the mean plasma HLA concentration was $1.47 \pm 0.87 \mu\text{g/mL}$ (mean $\pm$ SD). Platelet HLA concentrations of the same 61 persons ranged from 4.7 to $17.33 \text{ fg/platelet}$, and the mean concentration was $9.3 \pm 2.9 \text{ fg/platelet}$ (mean $\pm$ SD). The plasma HLA concentration of each individual was then correlated with his or her own platelet HLA concentration. Linear regression analysis²¹ showed no significant correlation between the two parameters ($r = .06$ and $P > 0.5$) (Fig 4).

HLA concentrations of chloroquine-treated platelets were also determined in 42 of the 61 volunteer donors. The quantities of chloroquine-elutable platelet HLA antigens were then calculated as the difference between HLA concentration of platelets before and after the treatment of chloroquine. The range of chloroquine-elutable platelet HLA antigens among the 42 individuals was 2.5 to 10.3 fg/platelet . The mean chloroquine-elutable platelet HLA was 5.7 ± 2.1

Fig 3. HLA contents of solubilized platelets. Different numbers of platelets were solubilized with $100 \mu\text{L}$ of lysing buffer. Amount of HLA antigen was measured by the enzyme-linked immunoassay. Each line represents platelets prepared from one individual.

EIA, enzyme-linked immunoassay; SBA, surface binding assay.

*SBA was performed by using ^{125}I -labeled W6/32 monoclonal Fab fragments and Scatchard analysis.⁴ The concentrations of platelets HLA were converted from molecules per platelet to femtograms per platelet. The mol wt of 56 kd for HLA antigens was used for calculation. There was no significant difference between HLA concentrations determined by the two assays ($P > .5$).

Fig 4. Quantitative correlation between plasma and total platelet HLA concentrations. Sixty-one normal adults were included in the study. Linear regression analysis revealed no significant correlation between the two parameters ($r = .06$, $P > .5$).

fg/platelet (mean $\pm$ SD). Again, no significant correlation was observed between chloroquine-elutable platelet HLA and the same person's plasma HLA concentration ($r = .03$ and $P > .8$). (Fig 5).

DISCUSSION

Although quantitation of plasma and platelet HLA antigens has been reported,^{9,12-14} these previous studies used inhibition of lymphocytotoxicity or platelet cytotoxicity as tests to measure relative rather than exact quantities of the HLA antigens. Theoretically, the degree of inhibition in those cytotoxicity assays is proportional to the actual quantity of HLA antigens. The HLA antigen concentrations determined can be affected, however, by microheterogeneity of the same serologically defined HLA antigen, by presence of undefined HLA antigens, and by cross-reactivity between different specific HLA antigens. Furthermore, the inhibition

Fig 5. Quantitative correlation between plasma and chloroquine-elutable platelet HLA concentrations. Chloroquine-elutable platelet HLA was determined as the difference of HLA concentration between platelets before and after chloroquine treatment. Forty-two subjects were available for the study. Linear regression analysis did not reveal any significant correlation between the two parameters ($r = .03$, $P > .8$).

of cytotoxicity assay measured only concentration of one specific type of HLA antigens at one time.

We describe competitive EIA for precise quantitation of total plasma soluble and platelet cellular HLA antigens. As shown in Table 1, the concentrations of platelet cellular HLA antigens that were determined by the competitive EIA were comparable with those determined by the surface binding assay using I^{125} -labelled Fab fragments of W6/32 anti-HLA McAb and Scatchard analysis. The results indicate that all the platelet HLA antigens measured by the competitive EIA were on the platelet surface, and there was no significant amount of HLA antigens in platelet cytoplasm. This finding is consistent with the absence of active protein synthesis in platelets. In contrast, the concentration of lymphocyte HLA antigens measured by the described competitive ELISA, was two to three times higher than that measured by the surface binding assay (data not shown). These differences are most likely due to the release of cytoplasmic HLA antigens from lymphocytes during solubilization. Thus, the HLA antigens measured in nucleated cells by the ELISA represent total cellular HLA antigens, which includes cytoplasmic and surface HLA antigens. The active synthesis of HLA antigens and the relatively fast turnover of membrane HLA antigens in lymphocytes²² are most likely responsible for the presence of high levels of HLA antigens in cytoplasm.

To test if the presence of anti-HLA antibodies in plasma samples from individuals with previous pregnancies or multiple blood transfusions might interfere with the assay, five of such plasma samples were assayed at $5\times$, $10\times$, and $20\times$ dilutions. Due to the presence of anti-HLA antibodies that interfered with the assay, the values obtained were not in parallel with the standard curve of the assay (data not shown). Therefore, to obtain a valid measurement of plasma or serum HLA concentration, it is imperative to assay all plasma samples at least at two different dilutions to exclude those samples containing interfering factor(s). All the plasma HLA concentrations assayed in this report were measured at $5\times$ and $10\times$ dilutions. The results were all in parallel with the standard curve.

According to the present study, the average plasma HLA concentration in normal adults is $1.47 \mu\text{g/mL}$. This number indicates that a significant amount of HLA antigens is present in the plasma of various blood components. Although the potential immunogenicity of plasma HLA antigens was reported,¹¹ the clinical significance of the quantitative variation of plasma HLA in allosensitization of recipients of plasma containing blood products remains unclear. The precise quantitation of plasma HLA antigens by using the developed assay will facilitate the study of plasma HLA immunogenicity.

Because previously platelet HLA-B12 antigen concentrations was shown to be proportional to plasma HLA-B12 content,⁹ that platelets can acquire plasma HLA antigens¹⁰ and that most platelet HLA is probably adsorbed on platelet surface,^{4,5} it has been speculated that the amounts of platelet-surface HLA would be directly proportional to plasma HLA levels. Results of the present study showed that there was no significant quantitative correlation between total platelet

and plasma HLA (Fig 4). Because it is possible that only the adsorbed platelet HLA may derive from plasma and may correlate to plasma HLA, quantities of adsorbed platelet HLA were then determined in 42 individuals by subtracting HLA concentration left on chloroquine-treated platelets from total platelet HLA content. Nevertheless, no quantitative correlation between plasma and adsorbed platelet HLA was observed (Fig 5). The results of the present study differed from the earlier observation made by Liebert and Aster.⁹ They reported that serum HLA-B12 antigens were roughly proportional to HLA-B12 on platelets. The small number of subjects (N = 5) included in their study and the assay method used may account for the differences.

In conclusion, the results we report highly suggest that the chloroquine-elutable platelet HLA antigens may not be derived from plasma and that platelet HLA concentration is not in dynamic equilibrium with plasma HLA. Therefore,

the quantitative expression of specific HLA antigens and the immunogenicity of platelets most likely could not be altered by incubating platelets with selected plasma. Although plasma HLA may not be the source of adsorbed platelet HLA, our results do not exclude the possibility that most platelet HLAs indeed may be adsorptive in nature. Further studies on the surface orientation and the physicochemical properties of chloroquine-elutable HLA antigens are needed to identify the origin and the adsorptive nature of platelet HLA antigens.

Non-Hodgkin's Lymphoma Containing Both B and T Cell Clones

By Eddie Hu, Lawrence M. Weiss, Roger Warnke, and Jeffrey Sklar

We describe a patient in whom two lymph node biopsies removed 18 months apart disclosed histologic and immunophenotypic evidence of a non-Hodgkin's lymphoma containing neoplastic lymphocytes of both B and T type. Analyses of immunoglobulin and T cell receptor genes confirmed the presence of separate B and T cell clones. In addition, immunogenotyping revealed the possibility of a second B cell clone within the patient's tumor. Development of a multiclonal lymphoma in this patient may relate

to the carcinogenic effects of chemotherapy or to a predisposition for neoplastic transformation of lymphocytes due to a previously diagnosed autoimmune condition. Another possible explanation is that the lymphoma implies the existence in this patient of a transformed lymphocyte-committed stem cell that is capable of generating both B and T lineage clones.

© 1987 by Grune & Stratton, Inc.

MOST NEOPLASMS are believed to consist of a single clone of neoplastic cells. A possible exception to this rule has recently been described among non-Hodgkin's lymphomas. Within a subset of these neoplasms, two proliferating clones of neoplastic B lymphocytes have been found in individual patients.^{1,2} Distinction between the clones in these cases was based on differences detected in the configurations of DNA in rearranged immunoglobulin genes. The results of immunoglobulin DNA analysis did not preclude a common origin of both clones from a single progenitor cell in which the immunoglobulin genes had not yet undergone DNA rearrangement, however. Furthermore, the interpretation of biclonality among B cell lymphomas has been complicated by the discovery that rearranged immunoglobulin genes in some B cell tumors can undergo somatic mutation.³ Occasionally, these mutations may alter the position of bands in Southern blot autoradiograms, thereby simulating differences in gene rearrangements among individual cells from a monoclonal tumor.

The lymphomas so far presented as candidates for biclonality have included only neoplasms composed exclusively of B cells. We report here a case of non-Hodgkin's lymphoma in which separate clones of B and T lymphocytes were detected using a combination of immunogenotyping and immunophenotyping techniques. Because clones of both B and T lineage were present in this tumor, deductions about multiclonality in this case are not affected by somatic mutation of rearranged genes, a process limited to immunoglobulin genes of B cells. In addition, in different biopsy specimens from this case, two different B cell populations were identified in which no shared rearrangements of immunoglobulin genes could be found. Therefore, this tumor may contain at a minimum two, and possibly as many as three, apparently distinct clonal lines of lymphocytes, which may or may not be related through a common precursor.

MATERIALS AND METHODS

Case report. The patient is a 63-year-old white woman who presented in 1981 with symptoms of diffuse myalgias, especially in her arms and legs, associated with peripheral eosinophilia. Subsequently, she developed a diffuse erythematous rash with induration and thickening of the skin, predominantly on the trunk and extremities. A biopsy of the skin and soft tissues of the left thigh was performed, and the histologic diagnosis of eosinophilic fasciitis was made. The patient was treated with systemic steroids, resulting in reduction of symptoms and improvement in the cutaneous lesions.

In June 1983, the patient developed diffuse peripheral lymphadenopathy and was first seen at the Stanford University Medical

Center. Biopsy tissue from an enlarged left axillary lymph node was diagnosed as containing diffuse large noncleaved cell lymphoma (DLCL). Staging workup revealed a normal bone marrow biopsy, but the bipedal lymphangiogram demonstrated extensive involvement of retroperitoneal lymph nodes, and a chest x-ray film showed bilateral nodular lesions consistent with lymphoma. The patient was classified as a stage IVA DLCL and treated from June to November 1983 with six cycles of CHOP (cyclophosphamide, adriamycin, vincristine, prednisone) chemotherapy, followed by the complete resolution of adenopathy and pulmonary nodules.

Soon after cessation of chemotherapy, the patient's initial skin lesions reappeared but responded to treatment with steroids combined briefly with small doses of cyclophosphamide. Late in 1984, she developed recurrent peripheral adenopathy. Biopsy of an enlarged left axillary lymph node in January 1985 revealed diffuse, mixed small and large cell lymphoma. Repeat staging indicated that her disease was confined to lymph nodes. Treatment was begun with BACOP (bleomycin, adriamycin, cyclophosphamide, oncovin, prednisone), producing a continued gradual regression of the patient's disease up to the present time.

Immunophenotype and immunogenotype studies. Biopsy tissues collected from the operating room were snap frozen in air-tight plastic capsules by immersion in a dry ice/isopentane bath and stored at -70°C . All tissues studied were obtained with the informed consent of the patient, in accord with institutional guidelines. Techniques for frozen-section immunoperoxidase studies have been described in detail elsewhere.⁴ Staining of frozen sections was performed using monoclonal antibodies directed against μ , κ , and λ immunoglobulin chains (Becton Dickinson, Mountain View, CA); Leu 1 through 5 (CD 2-5, 8) and 9 (CD 7) (Becton Dickinson); B1 (CD 20) (Coulter Clone, Hialeah, FL); 4G7 (CD 19) (Dr Ronald Levy, Stanford University); and TO15 (Dr David Mason, Oxford University).

DNA was extracted from tissue specimens and purified by standard procedures.^{5,6} Ten micrograms of DNA was digested with an appropriate restriction enzyme (New England BioLabs, Beverly,

Fig 1. Analysis of immunoglobulin and T cell receptor gene DNA. Autoradiograms resulting from analyses for rearrangements of immunoglobulin heavy chain genes (A) and T cell receptor genes (B). The hybridization probes used are indicated above each panel. Lane 1 shows analyses of DNA from the initial (1983) biopsy specimen; lanes 2a and 2b show analyses of DNA from the two parts of the second (1985) biopsy specimen. Dashes indicate unarranged germline bands; size of the corresponding fragments is given in kilobases. Arrows indicate clonal, rearranged bands. The lanes in each panel were assembled from different analyses. Within a panel, the analyses were made under similar conditions (including length of electrophoresis) and were aligned using marker bands run in parallel for each analysis, but not shown. Letters below each panel represent the restriction enzymes used in the analyses: H, *HindIII*; B, *BamHI*; S, *SacI*; and E, *EcoRI*. The analysis in the middle panel of B is identical to that in the panel to the left, except that electrophoresis was allowed to proceed for about four times as long.

MA) and the resulting fragments were analyzed by the Southern blot hybridization procedure.⁷ DNA probe fragments were radiolabeled with α -[³²P]-dCTP by the random hexamer priming method.⁸ Genomic DNA fragments used for analysis were specific for the heavy chain joining region, the constant and joining regions of the κ light chain gene, the constant region of the λ immunoglobulin light chain gene, the constant region for the β T cell receptor gene, and the joining region of γ T cell receptor gene. The structures of each of these probes has been described in detail previously,^{2,6,9-12} as have been methods for hybridization and autoradiography.^{6,9}

RESULTS

Analysis of this patient's neoplasm was based on tissue obtained from two lymph node biopsies—the initial diagnostic biopsy performed in June 1983 and the biopsy performed at relapse in January 1985. Histologic review of the lymph node biopsy specimen from 1983 showed complete effacement of the normal lymph node architecture by a polymorphous population of atypical small and large lymphoid cells. Large cells with vesicular noncleaved nuclei predominated in most areas examined, leading to the classification of the tumor as an intermediate grade, diffuse large noncleaved cell lymphoma according to the International Working Formulation for classification of non-Hodgkin's lymphoma.¹³

Immunoperoxidase studies on fresh-frozen tissues from this lymph node demonstrated that the large atypical cells expressed the B lineage antigens TO15, B1 (CD 20), and 4G7 (CD 19); however, staining for immunoglobulin light chains or μ heavy chain was absent. Similarly, the T cell antigens Leu 1 through 5 (CD 2–5, 8) and 9 (CD 7) could not be detected on these cells. In contrast, many of the smaller lymphocytes stained for normal patterns of T cell antigens. The immunologic findings were interpreted as consistent with a B lineage lymphoma lacking immunoglobulin expression, surrounded by a polyclonal T cell host response.

The B cell lineage of the neoplasm in this biopsy specimen was confirmed by analysis of immunoglobulin gene rearrangements (Fig 1, lane 1). Two clonal rearranged bands were detected in the analysis of the heavy chain gene DNA with one enzyme (*Hind*III), and a single rearranged band with a second enzyme (*Bam*HI). One clonal rearrangement was found in an analysis of the λ light chain gene DNA. Analysis of DNA for the β and γ T cell receptor demonstrated bands only in the position of unrearranged germline DNA. The results obtained with this tissue specimen are consistent with a monoclonal B lineage lymphoma, in which both heavy chain alleles were probably rearranged and one of the two λ light chain alleles was rearranged.

The 1985 lymph node biopsy specimen showed different histologic features from those noted in the previous biopsy specimen. The tumor population again consisted of a polymorphous population of atypical small and large lymphoid cells, with a tendency for the larger cells to be found clustered around vessels (Fig 2). Because the number of small and large cells in this specimen appeared to be more even, the tumor was classified as a diffuse, mixed small and large cell lymphoma.

Immunoperoxidase studies on the 1985 lymph node suggested two distinct subpopulations (Fig 3). Cells in some

Fig 2. Histologic appearance of the second (1985) lymph node biopsy specimen. The lymphoma varied in its morphology from field to field but generally consisted of a diffuse proliferation of atypical small and large lymphocytes. The specimen from this biopsy was diagnosed as a diffuse, mixed small cleaved and large cell lymphoma. (Hematoxylin and eosin stain, original magnification $\times 640$; current magnification $\times 475$.)

areas within the sections from this node, particularly in those areas adjacent to vessels, showed expression of the B lineage antigens TO15, B1 (CD 20), and 4G7 (CD 19), but did not express T cell antigens. This cell population failed to bind anti- λ , κ , or μ immunoglobulin antibodies. Cells in other areas of the sections expressed the T cell antigens Leu 1, 3, 4, and 5 (CD 2–5). Only scattered cells expressed Leu 2 (CD 8). Staining for Leu 9 (CD 7) on these cells was variable, from absent to moderate intensity on different cells. The immunologic findings in this lymph node biopsy specimen were interpreted as suggesting both a B cell lymphoma, based on the presence of immunoglobulin-negative B lineage cells, and a T cell lymphoma, based on the monotypic helper phenotype with abnormal, inconsistent staining for Leu 9 (CD 7).

Lymph node tissue from the 1985 biopsy had been divided into two parts (a and b) immediately after removal from the patient; tissue fragments representing the two parts of this specimen were separately analyzed for gene rearrangements (Fig 1, lanes 2a and b). Separate immunophenotypic studies were not available on these two portions of the 1985 biopsy. No clonal rearranged bands were detected in analyses of any immunoglobulin genes prepared with DNA extracted from tissue of part a. Analysis of the β T cell receptor gene demonstrated two closely migrating bands, however, one in the germline position and a second band slightly below the germline band. Analysis of γ T cell receptor genes in this tissue showed two rearranged bands, in addition to unrearranged, germline bands. Therefore, these data indicate a clonal population of T cells within this part of the specimen.

Examination of DNA from tissue of part b of the 1985 biopsy specimen produced different results. This tissue showed two clonal rearrangements in analyses of the immunoglobulin heavy chain gene with one enzyme (*Hind*III), and no detectable rearrangements with the other (*Bam*HI). A

Fig 3. Immunophenotype of the second (1985) lymph node biopsy specimen. In most areas of the specimen, the larger cells tended to cluster around vessels. Staining of the larger cells for the B lineage antigen 4G7 (CD 19) is apparent (A).¹⁴ Cells bearing the 4G7 antigen are surrounded by a dark ring of peroxidase reaction product. Other stains showed these cells to express other B lineage antigens, but not κ , λ , or μ immunoglobulin. Staining in a section similar to that in A of many of the smaller lymphocytes for the pan-T cell marker Leu 4 (CD 3) is apparent (B). These cells also expressed the pan-T cell antigens Leu 1, 3 and 5 (CD 2, 4, and 5), and showed anomalous staining for the T cell marker Leu 9 (CD 7) and occasional staining for Leu 2 (CD 8). (Original magnification of both A and B $\times 160$; current magnification $\times 145$.)

single clonal rearrangement was found for the λ light chain gene. Analyses of the β and γ T cell receptor genes produced results similar to those seen for part a. These findings imply that the T cell clone in part b was admixed with a B cell clone in part b.

None of the rearranged immunoglobulin gene bands detected in part b of the 1985 tissue matched those found in the earlier biopsy specimen, suggesting the emergence of a second clonal population of B cells in the patient. As a further test of the non-identity of the B cell populations, we investigated the configurations of DNA in the κ immuno-

globulin locus of these two tissues using a hybridization probe for the κ gene joining region.¹⁰ Although the κ constant regions in the clonal population of both specimens had apparently been deleted, the κ joining regions were retained and produced bands in different positions between the two tissues, as detected in analyses with *Sac*I, *Bam*HI, and *Hind*III enzymes (the latter two analyses not shown).

DISCUSSION

The histology and immunophenotyping of the two lymph node tissue samples in this case support the diagnosis of a non-Hodgkin's lymphoma containing B and T cell clones. DNA analyses confirmed the presence of separate clonal B and T cell populations in the second biopsy specimen. In addition, a possible distinction between the B cell clone in the first biopsy sample and the B cell clone in the later biopsy sample was demonstrated by analysis of DNA.

Past reports have described coexistent rearrangements of T cell receptor genes and immunoglobulin genes in the same cells within some lymphoid neoplasms.¹⁵⁻¹⁹ This cannot be the situation in the present case. Clonal rearrangements of the T cell receptor genes and immunoglobulin genes were both found in part b of the 1985 biopsy. Part a, however, contained only T cell receptor gene rearrangements in the absence of immunoglobulin gene rearrangements. The conclusion that T cell receptor and immunoglobulin gene rearrangements occurred in different cells is consistent with the immunophenotypic data, which showed separate B and T lineage populations among the histologically atypical cells of tissue sections.

On first appraisal, failure to detect any common immunoglobulin gene rearrangements between the two clonal B cell populations in this patient suggests that the two populations are unrelated or at least arose from a common precursor which lacked rearranged genes. As described previously, however, postrearrangement somatic mutations in immunoglobulin DNA may change the position of bands derived from a single recombination of immunoglobulin gene segments. Such changes may be extensive, affecting several different genes within a single monoclonal tumor (M.L. Cleary and J. Sklar, unpublished observations). In this regard, the immunophenotyping and DNA studies demonstrated noteworthy similarities among the two B cell populations in this patient. Both clones failed to express detectable levels of cellular immunoglobulins, a feature associated with $\sim 15\%$ of all large cell lymphomas. In addition, both populations showed rearrangements of lambda light chain genes, an occurrence in less than one-third of monoclonal B cell tumors.

On the other hand, extensive somatic mutation of immunoglobulin genes has so far been documented only in follicular B cell lymphomas, not in large cell lymphomas, such as in this patient. Moreover, differences in detectable rearrangements in this case extend even as far as the nonfunctional κ -genes that have undergone partial deletion. At present, it is not known if such nonfunctional genes are subject to somatic mutation, but whether or not these two apparently different B cell clones are actually mutational variants of the same

clone does not detract from the conclusion that a separate T cell clone was present within this patient's tumor.

Although the results of DNA analyses offer strong evidence for at least two different clones of lymphocytes in this patient's neoplasm, they do not specify the neoplastic nature of these clones. Could only one of the clones actually be neoplastic while the others represent immunologic reactions against the neoplastic clone? This seems unlikely for at least two reasons. First, detectable clonal proliferations of lymphocytes seem to be unusual outside of malignancy^{6,11} and have not previously been associated with immunological responses. Second, the immunophenotype of each clone was abnormal: Both B cell clones lacked immunoglobulin expression, and the T cell clone showed an anomalous, monotypic pattern of T cell antigens commonly found in peripheral T cell lymphomas.²⁰ In addition, the absence of detectable surface or cytoplasmic immunoglobulin from the B cell clones argues against their role in a normal immune response.

Several mechanisms could explain the occurrence of multiple clones of lymphocytes within this patient's tumor. One obvious possibility is that it is the result of a very rare coincidence in which two or three lymphocytes were independently transformed to malignancy more or less simultaneously. An interesting feature of this case, however, is that the patient initially had the rare autoimmune skin disorder, eosinophilic fasciitis.²¹ Lymphomas appear with greater than average frequency among patients with certain other autoimmune disorders, such as celiac disease,²² Sjögren's disease,²³ and chronic lymphocytic thyroiditis.²⁴ In addition, one patient with diffuse fasciitis has been described in whom a lymphoproliferative disorder was diagnosed at autopsy.²⁵ Therefore, one or more of the neoplastic lymphocytic clones detected within our patient may have developed as a result of a high rate of lymphocytic transformation due to autoimmunity.

Another possible cause for multiple clones in this patient's lymphoma is the chemotherapy she received after the diagnosis of her first neoplastic B cell clone. Most second neoplasms arising after chemotherapy are acute nonlymphocytic leukemias, although non-Hodgkin's lymphomas are also overrepresented among second tumors.²⁶⁻²⁸ The greatest increase in relative risk appears to occur among patients treated by combined radiation and chemotherapy. The interval from therapy to detection of the second cancer averages

between 3 and 10 years. Given these facts, the chance that our patient's therapy for her initial clone could have induced either or both of the other two clones does not seem great since she received neither radiation nor particularly intensive chemotherapy at any time. Moreover, the interval of ~18 months from the beginning of chemotherapy to diagnosis of the second and third clones was shorter than that in most cases of posttherapy second tumors.

Any speculation about chemotherapy-induced tumors in this patient must take into consideration that there are no published studies of second neoplasms in non-Hodgkin's lymphoma patients who have received the same CHOP regimen administered to the patient in this study. Furthermore, the ability to distinguish different clones of cells among neoplastic lymphocytes is a relatively recent development. Consequently, in the past, additional clones of neoplastic lymphocytes induced by therapy for non-Hodgkin's lymphoma would probably have been regarded as a relapse attributable to reemergence of the original clone. Therefore, induction of additional clones of neoplastic lymphocytes by chemotherapy may be more common in non-Hodgkin's lymphoma than is currently recognized.

A final possible mechanism to account for this patient's lymphoma is derivation from a single transformed early lymphocytic precursor. Lymphocyte-committed stem cells capable of generating both B and T cells are presumed to exist, although the evidence accumulated to date for this lymphocyte precursor is indirect. Among the best indications for the existence of such a cell is the deficiency of both B and T cells in patients with severe combined immune deficiency. More recently, the discovery of certain lymphocytic tumors containing a clone of cells that possess both immunoglobulin and T cell receptor gene rearrangements further supports existence of a lymphocytic stem cell. The possibility that the B and T cell clones in the present case of lymphoma arose from a single transformed cell may provide additional indirect evidence for a stem cell with pluripotential capacity for differentiation along both B and T cell lines.

Equal Stabilities of Normal β Globin and Nontranslatable β^0 -39 Thalassemic Transcripts in Cell-Free Extracts

By C.A. Stolle, M.S. Payne, and E.J. Benz, Jr

Patients with β^0 thalassemia arising from premature terminator codon mutations in the gene for β globin do not produce β globin protein; these individuals also exhibit a decreased amount of β globin mRNA in their erythroid cells. The absence of β globin protein is readily explained by the inability of the β^0 -39 mRNA to be translated. The decrease in β globin mRNA has been attributed to either decreased cytoplasmic stability of the nontranslatable mRNA or to an undefined nuclear lesion. To compare directly the relative stabilities of normal and β^0 -39 thalassemic globin transcripts, we prepared normal and thal-

semic β globin pre-mRNAs and mRNAs using cloned DNA templates and the SP6 promoter-polymerase system. The stability of the transcripts was assessed by incubation in various cell-free extracts. Our results indicate that although the stabilities of the β globin transcripts varied considerably from one extract to another the stabilities of the β^0 -39 thalassemic pre-mRNAs and mRNAs were equal to those of normal β globin mRNAs in every extract tested.

THE β THALASSEMIAS are inherited disorders characterized by reduced (β^+ thalassemia) or absent (β^0 thalassemia) synthesis of the β globin subunit of normal adult hemoglobin. Molecular cloning and nucleotide sequencing of numerous β -thalassemia genes have revealed a variety of mutations that impair β globin gene function in patients with β thalassemia. These mutations include partial gene deletions, impaired function of the transcription promoter region, errors in processing of β mRNA precursors (due either to alteration of the normal splice sites or to activation of "cryptic" splicing sites), and creation of premature translation termination codons that abolish translation of β^0 mRNA into β globin.^{1,2}

A translation termination mutation occurring at codon 39 (CAG $\rightarrow$ UAG) is a common cause of β^0 thalassemia among Greek and Italian patients.³⁻⁷ The β^0 thalassemia phenotype in homozygotes is clearly due to the inability of the β^0 -39 mRNA to be translated into β globin; however, the repeated observation^{4,6,8,9} that there is also a marked quantitative reduction in the amount of β globin mRNA in these patients' erythroid cells is not readily explained solely by the lesion in translation arising from this mutation. One frequently invoked hypothesis is that the inability of these mRNAs to be translated leads to accelerated nucleolytic degradation (instability) in the cytoplasm.^{4,10} Other possibilities include the presence of undetected mutations in sequences flanking the gene that affect transcription or processing, impaired nuclear to cytoplasmic transport, or decreased stability of the mRNA in the nucleus.^{11,12}

To address the question of whether normal and β^0 -39-thalassemic transcripts differ in their stability in the cytoplasm, we incubated synthetically prepared normal and thalassemic transcripts in various cell-free extracts. In this report, we describe the relative stabilities of these transcripts in vitro and discuss the lesion responsible for the decreased level of β globin mRNA in β^0 -39 thalassemia.

METHODS

Source of cells and cell-free extracts. Mouse erythroleukemia (MEL) cells (strain 745A) were maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS) (GIBCO, Grand Island, NY), 100 U/mL of penicillin, 100 μ g/mL of streptomycin, and 2 mmol/L of L-glutamine (GIBCO), at 37°C in a 5% CO₂ atmosphere. Cultures were split every 3 to 5 days to maintain a cell density of 1×10^4 to 1×10^6 cells/mL. HeLa cells

were grown to a density of 5×10^5 cells/mL in suspension culture in Spinner medium (KC Biologicals, Lenexa, KS) supplemented with 10% FCS, penicillin and streptomycin, and L-glutamine. Suspension cultures were flushed with 10% CO₂/90% air, capped, and incubated at 37°C.

Rabbit reticulocyte lysate translation reaction mixture (Bethesda Research Laboratories, Gaithersburg, MD) was prepared according to manufacturer's instructions. A HeLa whole cell extract capable of in vitro synthesis and splicing of pre-mRNAs was purchased from Bethesda Research Laboratories (eucaryotic In Vitro transcription system) and used according to manufacturer's directions, or prepared from HeLa cells and used according to the methods of Manley and colleagues.¹³ Nuclear and cytoplasmic extracts of MEL cells were prepared according to the method described by Dignam and co-workers¹⁴ for preparation of in vitro transcription lysates. Alternatively, cytoplasmic extracts of MEL cells were prepared by nitrogen cavitation¹⁵ to minimize release of lysosomal ribonucleases.

Plasmid construction. Construction of SP6 plasmids containing human β globin genes or cDNA sequences was accomplished as outlined in Fig 1. Plasmid pSPk β c, (a gift of Dr R. Spritz), was used as the parent vector. This plasmid contains a full-length, normal β globin cDNA plus SV40 sequences coding for a 175-base pair (bp) poly A tail. Transcripts prepared from pSPk β c are identical to naturally occurring β globin mRNA except for the presence of 20 non-globin bases in the 5' flanking region and a small number of bases in the 3' flanking region between the poly A tail and the HindIII restriction site.

Fig 1. Construction of plasmids. Plasmid pSPk β C contains the binding site for SP6 RNA polymerase (SP6), the coding region of a full-length normal β globin gene (shaded boxes), 20 bp of 5' flanking region as a result of cloning strategy (striped boxes), 175-bp sequence of SV40 DNA specifying a poly A tail (cross-hatched boxes), and a unique HindIII site. SP6 plasmids containing a β° -39 thalassemic cDNA or normal and β° -39 thalassemic genomic sequences were prepared by ligating the appropriate NcoI/EcoRI fragments into pSPk β C digested with NcoI and EcoRI. Intron sequences in the genomic clones are represented by open boxes.

Plasmids containing normal β globin or β° -39 thalassemic gene sequences were prepared by ligating a 1.35-kilobase (kb) NcoI/EcoRI fragment from appropriate subclones of normal β globin genes¹¹ into pSPk β C digested with NcoI and EcoRI. Likewise, an SP6 plasmid containing a β° -39 thalassemic cDNA was obtained by subcloning a 371-bp NcoI/EcoRI fragment from a β° -39 cDNA clone¹⁶ into pSPk β C digested with NcoI and EcoRI. The presence in the β° -39 parent plasmids of a C $\rightarrow$ T mutation at the codon for amino acid 39 was previously verified by DNA sequence analysis.^{11,16} All restriction enzymes and T4 DNA ligase were purchased from New England Biolabs (Beverly, MA).

Synthesis and Capping of SP6 transcripts. Labeled RNA transcripts were prepared according to the method of Green and colleagues.¹⁷ In brief, plasmid DNA was linearized with HindIII and transcribed at 37°C for 1 hour with SP6 RNA polymerase (New England Nuclear, Boston) in 40 mmol/L of Tris buffer (pH 7.5) containing 6 mmol/L of MgCl₂, 2 mmol/L of spermidine, 10 mmol/L of NaCl, 10 mmol/L of (DTT), RNasin (1 U/ μ L; Promega Biotech, Madison, WI), 500 μ mol/L of each rNTP, and 100 μ Ci of [³²P]-GTP (400 mCi/mmol; Amersham, Arlington Heights, IL). The DNA template was removed by digestion with RNAase-free DNAase (25 μ g/mL) for 15 minutes at 37°C. The RNA was then extracted with phenol:chloroform, centrifuged through a Sephadex G-50 column to remove unincorporated label, ethanol-precipitated, and resuspended in sterile distilled water. Typical yields were RNA 2 to 6 μ g/ μ g of DNA, with a specific activity of 1.7×10^7 dpm/ μ g RNA.

A 5'-terminal "CAP" structure [m⁷G(5')ppp(5')N] was added to the SP6 RNA transcripts with guanylyltransferase (1 U/ μ g RNA; Bethesda Research Laboratories) in a 30- μ L reaction containing 50 mmol/L of Tris-HCl (pH 7.9), 1.25 mmol/L of MgCl₂, 6 mmol/L of KCl, 3 mmol/L of DTT, RNasin (1 U/ μ L), 100 μ mol/L of S-adenosyl methionine, and 300 μ mol/L of GTP. After incubation at 37°C for 60 minutes, the reaction was extracted with phenol:chloroform and precipitated with ethanol. The resuspended transcripts migrated as a single band of either 1.8 kb (pre-mRNA) or 0.7 kb (mRNA) on denaturing agarose gels. The efficiency of the CAPPING reaction was estimated by determining survival of full-length RNA transcripts in a HeLa whole cell extract (Fig 2). Under the conditions used for these measurements, non-CAPPED mRNA is rapidly degraded but CAPPED mRNA is completely preserved. For the experiments described in this report, only preparations exhibiting 80% to 100% stability in HeLa extract after CAPPING were used. Other methods of capping, such as inclusion of CAP analogues in the polymerization reaction, did not result in efficient synthesis of

Fig 2. Stability of RNA transcripts $\pm$ 5' terminal CAP in HeLa cell extract. Equal amounts of CAPPED and non-CAPPED RNA transcripts were incubated at 30°C in a HeLa whole cell extract prepared according to the method of Manley and colleagues.¹³ Samples removed at the time points indicated were processed for electrophoresis as described in Fig 4. Panel A, pre-mRNA; panel B, mRNA; β cap and β° cap, CAPPED normal and thalassemic transcripts; β and β° , non-CAPPED normal and thalassemic transcripts; M, RNA size markers. Aliquots from incubations containing pre-mRNAs (panel C) or m-RNAs (panel D) were taken at the time points indicated and spotted onto DE-81 filters. The filters were washed successively with 0.5 mol/L of Na₂HPO₄, dH₂O, and ethanol, and then dried and counted in a scintillation counter. The counts were plotted as a percentage of the input RNA remaining v time.

full-length transcripts. RNAs modified at the 5' end are referred to in this article as CAPped; RNAs not modified in this way are referred to as non-CAPped. The RNA transcripts were synthesized with poly A tails and 5' CAPS since both are naturally occurring modifications believed to affect mRNA stability.

Stability in cell-free extracts. The stability of the labeled transcripts was assessed by incubating equal amounts of RNA in cell-free extracts for up to 2 hours. A 2-hour incubation period was chosen on the basis of earlier studies from our laboratory,¹¹ that showed that intact erythroid cells from a patient with a β^0 -39 thalassemia gene exhibited a reduction of newly synthesized β globin mRNA to steady-state thalassemic levels within 20 minutes after exposure to [³H]-uridine. Therefore, any mRNA turnover relevant to whole cells should occur well within our 2-hour observation period.

A typical assay for in vitro stability consisted of 3×10^5 cpm of RNA (20 ng) in 30 μ L of cell extract. Aliquots taken at time points during the incubation were diluted in 300 μ L of TE buffer (10 mmol/L of Tris-HCl, pH 7.5; 1 mmol/L of EDTA), extracted with phenol:chloroform, ethanol precipitated, and resuspended in a small volume of sterile dH₂O. The samples were mixed with 3 vol of a denaturing buffer containing 50% deionized formamide, 17% formaldehyde, and 1x MOPS buffer (40 mmol/L of morpholinopropanesulfonic acid, pH 7.0; 10 mmol/L of sodium acetate; 1 mmol/L of EDTA), heated to 65°C for 10 minutes, and electrophoresed on a 1.5% agarose gel containing 6.7% formaldehyde in 1x MOPS buffer. The labeled RNA bands were transferred to nitrocellulose paper by a Northern blotting procedure,¹⁸ and the blots were exposed to x-ray film (Kodak XAR-5). To quantitate the stability of labeled RNA in the cell extracts, aliquots were spotted directly onto Whatman DE-81 filters, washed six times with 0.5 mol/L of Na₂ HPO₄, twice with dH₂O, and twice with 95% ethanol. The filters were then air dried and counted in a scintillation counter. The stability of the RNA was plotted as the percentage of labeled RNA (cpm) bound to the filter v time.

Cell-free translation. CAPped normal β globin and β^0 -39 thalassemic mRNAs (200 to 500 ng) were translated in a rabbit reticulocyte lysate in vitro translation system (Bethesda Research Laboratories) according to the manufacturer's specifications. The translation products were labeled with either [³⁵S]-methionine (5 μ Ci/reaction) or [³H]-leucine (5 μ Ci/reaction). The labeled proteins were electrophoresed on a 12.5% polyacrylamide slab gel containing 6 mol/L of urea, 2% Triton X-100, and 5% acetic acid^{19,20} along with unlabeled human globin chains as markers. The gel was either stained with Coomassie blue and destained in 5% acetic acid and 25% methanol or processed for fluorography with Enlightening (New England Nuclear), dried on a slab gel dryer, and exposed to x-ray film.

Splicing of normal β globin and β^0 -39 thalassemic pre-mRNAs. CAPped normal β globin and β^0 -39 thalassemic pre-mRNAs were incubated for 4 hours at 30°C essentially as described by Krainer and associates²¹ in an in vitro splicing extract prepared from HeLa cells by the method of Dignam and associates.¹⁴ The splicing products were electrophoresed on a denaturing 5% polyacrylamide gel and visualized by autoradiography.

RESULTS

Verification of SP6 plasmid construction. Construction of SP6 plasmids containing normal β globin and β^0 -39 thalassemic globin sequences was verified by digestion with the restriction enzyme Mae I. Mae I recognizes the sequence C/TAG; a new Mae I site is created by a single C $\rightarrow$ T conversion at the codon for amino acid 39 in exon 2 of the β globin gene. The position of relevant Mae I sites and the size

of the expected digestion fragments is diagrammed in Fig 3A. All constructs (normal and β^0 thalassemic pre-mRNAs and mRNAs) were digested with Mae I, and the products were electrophoresed on a 1% agarose gel. Southern blot analysis of the digestion products using a nick-translated 430-bp NcoI/BamHI probe specific for sequences spanning the β^0 -39 mutation is shown in Fig 3B. As expected, digestion of the normal β globin gene construct produced an 800-bp band; the β^0 -39 thalassemic gene construct yielded bands at 520 bp and 280 bp instead of the 800-bp fragment, reflecting the presence of the new Mae I site introduced by the β^0 -39 mutation. Similarly, digestion of β globin cDNA constructs resulted in a 1.4-kb band from pSPk β c or a 1.26-kb band from pSP6 β^0 c.

Stability of RNA transcripts in a rabbit reticulocyte lysate. Equal amounts of CAPped and non-CAPped, normal β , and β^0 -39 thalassemic transcripts were incubated in a translationally competent rabbit reticulocyte lysate. The β globin transcripts were largely stable in the reticulocyte lysate, since considerable amounts of full-length transcripts were present even after 2 hours of incubation (Fig 4). Some RNA degradation did occur, however, resulting in the loss of 15% to 25% of the labeled RNA as measured by DE-81 filter counts (data not shown). There was no difference in stability

Fig 3. Digestion of β globin constructs with Mae I. Construction of the SP6 plasmids containing normal β and β^0 -39 thalassemic globin sequences was verified by digestion with Mae I. Schematic diagram showing position of Mae I sites in the β globin gene and cDNA plasmid inserts, the size of the fragments expected on digestion of the normal β and β^0 -39 plasmid constructs with Mae I, and the origin of a 430-bp NcoI/BamHI probe (A). Southern blot of Mae I digest hybridized to nick-translated 430-bp NcoI/BamHI fragment from the β globin gene (B). β_0 and β^0 , fragments derived from the normal β globin or β^0 -39 thalassemic gene sequences, respectively; β_0 and β^0 , fragments derived from the normal or thalassemic cDNA sequences, respectively.

Fig 4. Stability of RNA transcripts in rabbit reticulocyte lysate. Equal amounts of normal and β° -39 thalassemic transcripts were incubated in a rabbit reticulocyte lysate translation mixture for 2 hours at 30°C. Aliquots were removed after 0, 30, 60, and 120 minutes, extracted with phenol:chloroform, precipitated with ethanol, and resuspended in a small volume of sterile dH_2O . The samples were denatured and electrophoresed on a 1.5% agarose gel containing formaldehyde. The mRNA was transferred to nitrocellulose paper, and the filter was exposed to x-ray film. The faint band of labeled material migrating below full-length pre-mRNA is an artifact of electrophoresis seen occasionally in reticulocyte extracts. Panel A, pre-mRNA; panel B, mRNA; β cap, CAPped normal β globin transcript; β , non-CAPped normal β globin transcript; β° , non-CAPped β° -39 thalassemic transcript; M, RNA size markers.

between normal β globin and β° -39 thalassemic pre-mRNAs (Fig 4A) or mRNAs (Fig 4B).

The stability of the RNA transcripts in reticulocyte extract was independent of translational activity by several lines of evidence. In addition to the β° -39 transcripts, other nontranslatable messages, such as pre-mRNAs (containing introns) and non-CAPped mRNAs (unable to interact with translation initiation factors), were also as stable in the rabbit reticulocyte translation mixture as were translatable CAPped mRNAs (Fig 4). Furthermore, all RNA transcripts were equally stable in a rabbit reticulocyte lysate prepared without creatine phosphate and the amino acids required for translation (data not shown).

Stability of RNA transcripts in a HeLa whole cell extract. In a HeLa whole cell extract, prepared as an *in vitro* transcription extract by the method of Manley and co-workers,¹³ a difference in stability between CAPped and non-CAPped transcripts was evident. CAPped pre-mRNAs (Fig 2A) and mRNAs (Fig 2B) were relatively stable for up to 2 hours in the HeLa cell extract whereas non-CAPped transcripts were readily degraded. Autoradiographs of dena-

turing agarose gels revealed that no full length non-CAPped transcripts remained after 30 minutes of incubation. The stability of CAPped transcripts in the HeLa cell extract was not dependent on protection from ribonuclease attack by polysome formation (ie, translation), since the extract is prepared by ammonium sulfate precipitation of nuclear and cytoplasmic proteins and is devoid of ribosomes. More important, there was no difference in the stability of CAPped normal or thalassemic transcripts or in the rate of degradation of non-CAPped normal or thalassemic transcripts as assessed by DE-81 filter counts (Fig 2C and D). Although the HeLa cell extract clearly had the potential to degrade RNA transcripts, no difference in stability was detected between normal β globin and β° -39 thalassemic transcripts.

Stability of RNA transcripts in MEL cell extracts. Nuclear and cytoplasmic extracts of MEL cells were prepared by several methods to examine the stability of globin transcripts in extracts reflecting an erythroid progenitor cell environment. The stability of β globin transcripts in the MEL cell extracts varied with the method of preparation. For example, the stability of β globin transcripts in nuclear

extracts of MEL cells prepared by the method of Dignam and associates¹⁴ or cytoplasmic extracts of MEL cells prepared by nitrogen cavitation was comparable to that of β globin transcripts in rabbit reticulocyte lysates (data not shown).

In contrast, each of the RNA transcripts exhibited rapid degradation (as assessed by DE-81 filter counts) in an S-100 cytoplasmic extract¹⁴ prepared from uninduced MEL cells. Both pre-mRNAs (Fig 5A) and mRNAs (Fig 5B), regardless of 5' CAP status, were degraded. There was no difference in stability between normal β globin and β^0 -39 thalassemic transcripts, even at time points <20 minutes. Although 50% of the input RNA was still able to bind to DE-81 filters after 60 minutes of incubation, no full-length message remained (Fig 6, MELC). This result contrasts with the relative preservation of full-length RNA observed after a comparable exposure to reticulocyte lysate (Fig 6, RRL).

Fig 5. Stability of pre-mRNAs and mRNAs $\pm$ 5' terminal CAP in MEL cell extract. An S-100 cytoplasmic fraction was prepared from MEL cells by the method of Dignam and colleagues.¹⁴ The stability of labeled RNAs was assessed by DE-81 filter counts as described in Fig 4. Pre-mRNAs (A); mRNAs (B); β_G CAP and β_G CAP, CAPped normal β globin transcripts; β_G and β_G , non-CAPped normal β globin transcripts; β_G^0 and β_G^0 , non-CAPped thalassemic transcripts.

Fig 6. Stability of SP6 transcripts in MEL cell cytoplasmic extracts after preincubation in rabbit reticulocyte lysate translation mixture. CAPped β globin mRNA was preincubated in a rabbit reticulocyte lysate for 15 minutes before the addition of an equal volume of MEL cell extract. Aliquots taken at time points after addition of the cytoplasmic extract were electrophoresed on a denaturing agarose gel as described in Fig 3. MELC, mRNA incubated in MEL cell extract alone; RRL:MELC, mRNA preincubated in a rabbit reticulocyte lysate before addition of MEL cell extract; RRL, mRNA incubated in rabbit reticulocyte lysate alone.

S-100 cytoplasmic extracts prepared from MEL cells induced with dimethylsulfoxide (DMSO) or hemin degraded RNA transcripts as rapidly as did cytoplasmic extract from uninduced MEL cells (data not shown). Addition of up to 16 U/ μ L of RNasin failed to inhibit the ribonuclease activity of the MEL cell extract. In no case did we ever encounter any differences in stability between normal β globin and β^0 thalassemic transcripts in any of the MEL cell extracts tested.

Because the MEL cell S-100 extract lacked ribosomes, we examined whether prebinding the mRNAs to ribosomes would improve mRNA stability in this extract. Preincubating CAPped mRNAs in a fully active rabbit reticulocyte translation mixture before adding MEL cell cytoplasmic extract failed to enhance the survival of the mRNAs substantially (Fig 6). The stability (or lability) of the mRNAs was, therefore, independent of translational activity in this extract.

Translation of normal β and β^0 -39 thalassemic mRNAs. To demonstrate the activity of the rabbit reticulocyte lysate and the translatability of the synthetic β globin transcripts, we incubated CAPped normal β globin and β^0 -39 thalassemic mRNAs in a rabbit reticulocyte lysate in vitro translation system and labeled the newly synthesized peptides with either [³H]-leucine or [³⁵S]-methionine. The translation products were mixed with unlabeled human globin chains and separated by electrophoresis in a 12.5% polyacrylamide gel containing Triton X-100 (New England Nuclear), acetic acid, and urea.^{19,20} This electrophoretic system separates proteins by charge and not necessarily by molecular size.

Normal β globin mRNA promoted synthesis of a protein that comigrated with normal human β globin chain (Fig 7, lanes 3 and 7). Translation of the β° -39 thalassemic mRNA in the presence of [^{35} S]-methionine, as expected, failed to produce any labeled peptide (Fig 7, lane 4), since the β globin chain contains a single methionine residue at amino acid 55, carboxy-terminal to the β° -39 thalassemia mutation.

Interestingly, however, the β° -39 thalassemic mRNA was able to produce a labeled peptide when incubated in the presence of [^{3} H]-leucine (Fig 7, lane 9). The translation product of β° -39 mRNA migrated faster than did normal β chains on Triton-acid-urea gels. It is tempting to speculate that the abnormally migrating β° -39 peptide is a β globin chain terminated by the translation stop codon at amino acid 39. The amount of material generated by cell-free translation precluded complete characterization of the abnormal peptide, however. The production of a labeled peptide by β° -39 thalassemic mRNA indicates that this message can interact with the translational apparatus and suggests that the β° -39 transcript may initiate polysome formation in vivo.

Splicing of normal β and β° -39 thalassemic pre-mRNAs. CAPped normal β globin and β° -39 thalassemic pre-mRNAs were spliced essentially as described by Krainer and co-workers²¹ in a HeLa cell nuclear extract,¹⁴ and the splicing products were separated on a denaturing 5% polyacrylamide gel (Fig 8). The intensities of the bands representing spliced exon 1 and 2, as well as exon 1 (cleaved but not spliced), from both normal β globin and β° -39 thalassemic pre-mRNAs are virtually equal, indicating that both pre-mRNAs are spliced to the same extent within 4 hours. The mutation at codon 39 near the 5' end of exon 2 in β° -39

Fig 7. Translation of normal and β° -39 globin mRNA in a rabbit reticulocyte lysate. CAPped normal and β° -39 mRNA transcripts prepared from SP6 templates were translated in a rabbit reticulocyte in vitro translation system and labeled with [^{35} S]-methionine or [^{3} H]-leucine. The translation products were mixed with unlabeled adult human hemoglobin standards and electrophoresed on a 12.5% polyacrylamide gel containing acetic acid, urea, and Triton X-100. The gel was stained with Coomassie blue, processed for fluorography, dried, and exposed to x-ray film. Lanes 1 and 5, no mRNA; lanes 2 and 6, rabbit globin mRNA; lanes 3 and 7, normal β globin mRNA; lanes 4 and 8, β° -39 thalassemic mRNA; lane 9, longer exposure of lane 8. The mobilities of human α and β globin chain standards are noted (right).

Fig 8. Splicing of normal and β° -39 globin pre-mRNA. CAPped normal β globin (β) and β° -39 thalassemic (β°) pre-mRNAs were electrophoresed on a denaturing 5% polyacrylamide gel before (–) or after (+) incubation in HeLa cell nuclear extract essentially as described by Krainer and colleagues.²¹ Position of RNA size markers is indicated (left). – Ex1 Ex2, product of splicing exons 1 and 2; – Ex1, fragment resulting from cleavage of exon 1 without splicing to exon 2. Arrow indicates position of unspliced pre-mRNA.

thalassemic pre-mRNA does not affect splicing of exons 1 and 2.

No appreciable splicing of exons 1 through 3 was observed in this reaction with either pre-mRNA. Humphries and colleagues,¹² however, and other researchers (S. Baserga and E.J. Benz, Jr, unpublished) have confirmed that β° -39 thalassemic pre-mRNAs in transfected cell lines are spliced as efficiently as normal β globin pre-mRNAs using an M13 probe covering exons 1, 2, and 3. Therefore, β° -39 thalas-

semic pre-mRNAs do not exhibit a defect in processing which might lead to their abnormal accumulation or degradation in the nucleus.

DISCUSSION

Decreased levels of β thalassemic mRNAs in the cell cytoplasm have been attributed either to degradation of nontranslatable message by ribonucleases in the cytoplasm,^{4,10} or to an intranuclear defect.^{11,12} Previous studies of the cytoplasmic stability of β^0 -39 transcripts in vivo and in transfected cells (using pulse-label and chase or actinomycin D chase techniques) indicated that the β^0 -39 mRNA was stable in the cytoplasm.^{11,12} It is difficult to draw firm conclusions from these results, however, because of the technical limitations inherent in the methods. The number of counts per minute that can be incorporated into globin mRNA in intact cells during a pulse-label is small; moreover, actinomycin D can affect other intracellular processes that can alter mRNA degradation rates.²² For these reasons, intact cell labeling studies cannot be used to distinguish short-term stability defects from transcription or processing phenomena. We have therefore examined the relative stabilities of normal β globin and β^0 -39 thalassemic transcripts using in vitro synthesized RNA transcripts and various cell-free extracts and, in particular, have addressed the question of whether translation of a β globin transcript affected its stability.

For this study, normal β globin and β^0 -39 thalassemic RNA transcripts were prepared which resembled authentic globin transcripts in that they could be CAPped, bound to oligo dT columns (not shown), translated, and spliced. The cell-free extracts chosen for study were ones previously developed to study discrete steps in RNA metabolism, such as translation, transcription, or splicing. Recently, Ross and Kobs²³ demonstrated the usefulness of such cell-free systems for detecting differences in stability of various mRNAs. In our cell-free systems, we found no difference in the relative stabilities of normal β or β^0 -39 thalassemic pre-mRNAs or mRNAs regardless of the translational potential of the extract or translatability of the RNA transcript.

The various cell-free extracts we examined exhibited quantitative and qualitative differences in ribonuclease activity. The rabbit reticulocyte lysate exhibited relatively little ribonuclease activity, consistent with its function as a translation extract. Some degradation did occur, however,

suggesting that the stability we observed was not merely the result of the EGTA used in the preparation of the lysate to inhibit micrococcal nuclease. Incubation in the rabbit reticulocyte lysate resulted in equal survival of both CAPped and non-CAPped transcripts. The HeLa whole cell extract, however, was capable of degrading non-CAPped transcripts. The 5' CAP structure is believed to protect CAPped transcripts from a 5' to 3' exoribonuclease,²⁴⁻²⁶ which is apparently the major ribonuclease activity in the HeLa cell extract. The MEL cell cytoplasmic extract, in contrast, was capable of degrading both CAPped and non-CAPped transcripts. The inability of the 5' CAP structure to protect transcripts in the MEL cell extract suggests that this extract contains potent endoribonuclease or 3' to 5' exoribonuclease activity not present in the HeLa cell extract. The clipping action of an endoribonuclease as opposed to the processive action of a 5' to 3' exoribonuclease might account for the fact that degradation of labeled RNA transcripts in the MEL cell extract resulted in a high percentage of fragments still capable of binding to a DE-81 filter as compared with the HeLa cell extract. Despite the differences in ribonuclease activity inherent in each cell-free extract, however, no extract was capable of preferentially degrading β^0 -39 thalassemic transcripts under any conditions tested.

The results reported here suggest that the stability of β^0 -39 mRNA is not dependent on polysome formation and that thalassemic RNA transcripts can be stable in the absence of translation. The recent observation by Baserga and colleagues²⁷ that there were no differences in stability between normal β globin and β^0 -39 thalassemic mRNAs in transfected cells containing a temperature-sensitive RNA polymerase, on incubation of the cells at the nonpermissive temperature, is consistent with our findings. Taken together, our results and those of others^{11,12,27} suggest that the decreased levels of β^0 -39 mRNA in patients' erythroid cells is not due to decreased cytoplasmic stability, but rather to some more "proximal" process such as transcription, nuclear stability, or nuclear to cytoplasmic transport.

ACKNOWLEDGMENT

We gratefully acknowledge Dr Richard Spritz for his gift of plasmid pSPk β c, Dr Steven Liebhaber for his gift of a β^0 -39 cDNA clone, Dr Prabhat Ghosh for HeLa cell extracts, Sharlene Ivory for excellent technical assistance, and Linda Boynton and Nicole Wade for preparation of the manuscript.

Biosynthesis and Secretion of Functional Protein S by a Human Megakaryoblastic Cell Line (MEG-01)

By Michinori Ogura, Noboru Tanabe, Junji Nishioka, Koji Suzuki, and Hidehiko Saito

A human megakaryoblastic cell line (MEG-01) was investigated for the presence of protein S in culture medium and cell lysates using a specific enzyme-linked immunoassay (ELISA) and a functional assay. When 5×10^5 MEG-01 cells/mL was subcultured in RPMI 1640 medium with 10% fetal calf serum (FCS), the concentration of protein S antigen in the culture medium increased progressively with time from <8 ng/mL on day 0 to 105.6 ± 6.0 ng/mL on day 13. Vitamin K₂ ($1 \mu\text{g/mL}$) increased the production of functional protein S, whereas warfarin ($1 \mu\text{g/mL}$) profoundly decreased the quantity and the specific activity of secreted protein S. By an indirect immunofluorescent technique, protein S antigen was detected in both MEG-01 cells and human bone marrow megakaryocytes. Immunoblot analysis of culture medium revealed two distinct bands (mol wt

84,000 and 78,000) that are identical to the doublets of purified plasma protein S. De novo synthesis of protein S was demonstrated by the presence of specific immunoprecipitable radioactivity in the medium after 5 hours of labeling of the cells with [³⁵S]-methionine as a 84,000 mol wt protein. Plasma protein S levels of nine patients with severe aplastic anemia were not significantly different from those of normal controls. These results suggest that megakaryocytes produce functional protein S and contain the enzymes required for the carboxylation of selected glutamic acid residues, and that protein S synthesized by megakaryocytes does not represent a main source of plasma protein S.

© 1987 by Grune & Stratton, Inc.

PROTEIN S is a vitamin K-dependent single chain plasma glycoprotein that is required for optimal expression of the anticoagulant activity of another vitamin K-dependent protein, activated protein C (APC).¹ The physiologic importance of protein S as an anticoagulant is clearly illustrated by the association of hereditary protein S deficiency and thrombosis.² Recent studies have shown that a human hepatoma cell line, and human and bovine endothelial cells synthesize and secrete protein S.³⁻⁵ Schwarz and colleagues⁶ identified protein S in α granules of human platelets, which suggests that the released protein S may bind to stimulated platelets and thereby promote and localize the anticoagulant activity of APC on the platelet surface. Although protein S was recently observed in human megakaryocytes by immunochemical staining,⁷ it is not known whether megakaryocytes can synthesize protein S, since megakaryocytes may acquire some α -granule proteins from plasma by endocytosis.⁸ In this article, we report that a well-characterized human megakaryoblastic cell line, MEG-01,⁹ synthesizes and secretes functional protein S, which can be modulated by vitamin K and warfarin. A preliminary part of this study has been published in abstract form.¹⁰

MATERIALS AND METHODS

Human protein S, monospecific rabbit antiserum against protein S, and citrated plasmas of 25 normal volunteers and nine patients with severe aplastic anemia were prepared as described.¹¹ A monospecific rabbit antiserum against von Willebrand factor (vWf) was obtained from Dakopatts, Grostrup, Denmark.

Cell culture. The establishment and several properties of a human megakaryoblastic cell line, MEG-01, have been previously described in detail.⁹ MEG-01 cells possessed no markers for B or T lymphocytes or for myeloid cells. They demonstrated many megakaryocytic characteristics.⁹ Additional studies showed that cell surface glycoprotein A was not demonstrated by an indirect immunofluorescent technique using mouse anti-human glycoprotein A monoclonal antibody (Immunotech, Marseille, France), indicating the absence of the erythroid antigen. MEG-01 cells were grown in RPMI 1640 medium supplemented with 10% heat inactivated fetal calf serum (FCS, Flow Laboratories, Stanmore, New South Wales, Australia), 100 U/mL aqueous penicillin G, and 50 $\mu\text{g/mL}$ streptomycin. In some experiments, serum-free medium (HB101, Hana

Media, Berkeley, CA) was also used. The cells were seeded in Falcon 3013 plastic tissue culture flasks (Falcon, Division of Becton Dickinson, Oxnard, CA) at 2 to $5 \times 10^5/\text{mL}$ in 8 mL of medium. In selected experiments, the cells were treated with vitamin K₂ (Kayt-wo, Eisai, Tokyo; $1 \mu\text{g/mL}$) or warfarin derivative (3-(α -acetylbenzyl)-4-hydroxycoumarin potassium salt, warfarin potassium, Eisai, $1 \mu\text{g/mL}$) for 7 to 14 days in RPMI 1640 medium with 10% FCS or in HB101 serum-free medium. Aliquots (1.8 mL) were removed daily or every 2 to 3 days, and the same volume of fresh medium was replaced. Harvested medium was mixed with 0.2 mL of phosphate-buffered saline, pH 7.0, (PBS) containing 500 mmol/L of benzamide hydrochloride (Sigma Chemical, St Louis) and 10 mmol/L of diisopropyl fluorophosphate (DFP, Sigma), and was centrifuged at 15,000 rpm for 10 minutes at 4°C. The supernatants were stored at -80°C until analysis. Cell pellets were suspended in cold PBS containing protease inhibitors described above and 0.1% Triton X-100 (Sigma) and frozen and thawed twice. Cells were further disrupted by an ultrasonic cell disruptor (Sonifier, model 200, New York), and were centrifuged at 15,000 rpm for 10 minutes. The supernatants of cell lysates were also frozen until use. Spent medium and cell lysates of other human cell lines such as HL-60 (promyelocytic leukemia cell line), K-562 (erythroleukemia cell line), MOLT 4 (T lymphoblastic leukemia cell line), and U-937 (histiocytic lymphoma cell line) were used as controls for MEG-01.

Assay of protein S antigen. Protein S was determined by the sandwich-type enzyme-linked immunoassay (ELISA) using mono-

specific rabbit anti-protein S F(a,b')₂ fragment coupled with β -D-galactosidase that had been prepared as described.¹² Assays were performed at room temperature. Flat-bottomed ELISA plate wells were coated with the F(a,b')₂ fragment (10 μ g/mL) in 0.1 mol/L of phosphate buffer, pH 8.0. After 1 hour of incubation, unbound materials were removed by washing with the phosphate buffer. The wells were then blocked with 200 μ L of 10% normal rabbit serum for 2 hours. The wells were washed three times with PBS (0.01 mol/L of phosphate buffer, 0.1 mol/L of NaCl, 1 mmol/L of MgCl₂, pH 7.0) containing 0.1% bovine serum albumin (BSA). Then 100 μ L of sample solution, diluted appropriately in PBS containing 0.1% BSA, was added and incubated for 2 hours. After being washed three times, 100 μ L of the F(a,b')₂ fragment coupled with β -D-galactosidase was added and incubated for 1 hour. After being washed, 100 μ L of freshly prepared substrate solution, 0.1 mg/mL of 4-methyl-umbelliferyl- β -D-galactoside (Sigma) in the PBS, was then added to the wells, and the enzyme reaction was allowed to proceed for 30 minutes. Fluorescence of each well was determined at 360 nm excitation and 450 nm emission using Fluororeader (Dynatech Laboratories, Inc, Alexandria, VA). By this ELISA, protein S 1 to 100 ng/mL was measured with high specificity and reproducibility. Protein S antigen of plasmas from the patients with aplastic anemia and normal controls was measured by the Laurell electroimmunoassay as described.¹¹

Functional assay of protein S. The culture medium was concentrated 20-fold with Centricon (Amicon, Danvers, MA), and then dialyzed against 0.05 mol/L of Tris-HCl, 0.1 mol/L of NaCl, pH 7.5. Preliminary experiments showed that 97% protein S was recovered during concentration and dialysis when known amounts of purified protein S were added to the culture medium before concentration. Protein S activity was assayed by determining the ability of protein S to function as a cofactor of the anticoagulant effects of activated protein C as described earlier.¹¹ The standard curve was prepared by substituting the culture medium with protein S-depleted plasma containing varying amounts of purified protein S (0, 0.31, 0.63, 1.25, 2.5, 5, 10 μ g/mL). The fresh culture medium with 10% FCS contained no significant amount of protein S activity.

Immunoblotting analysis of protein S in culture medium. Culture medium (35 mL) was mixed with 2 mL of the agarose coupled with anti-protein S-IgG (2 mg of IgG/mL of agarose) at room temperature for 4 hours in a rolling bottle. The agarose was then packed in a column (0.9 $\times$ 6 cm) and washed with 20 mL of 0.05 mol/L of Tris-HCl, 0.1 mol/L of NaCl, pH 7.5. Proteins bound to the agarose were then eluted with 0.05 mol/L of Tris-HCl, pH 7.5, containing 8 mol/L of urea. Protein S in the eluate was examined with sodium dodecyl sulfate (SDS)-polyacrylamide gradient (7.5% to 15%) slab gel electrophoresis¹³ in the presence of a reducing agent, followed by the Western blotting technique using anti-protein S-serum, as previously described.¹⁴

Immunoprecipitation. Incorporation of [³⁵S]-methionine into protein S was studied as described.¹⁵ In brief, cultures of MEG-01 cells were washed with methionine-free minimal essential medium (Nissui Seiyaku, Tokyo) and were then incubated in 5 mL of the same medium supplemented with 1 mCi [³⁵S]-methionine (Amersham, Arlington Heights, IL) for 5 hours at 37°C. Protein S was immunoprecipitated from the medium by the method of Kessler.¹⁶ The immunoprecipitates were eluted from formaldehyde-fixed *Staphylococcus aureus* Cowan strain II (Pansorbin, Calbiochem-Behring, La Jolla, CA) by boiling and then electrophoresed on SDS-9% polyacrylamide gel electrophoresis (PAGE). Gels were stained, destained, and then treated with Enlightening (New England Nuclear, Boston) before autoradiography.

Immunofluorescence staining. Bone marrow specimens were obtained from patients with nonmyeloproliferative disorders after informed consent. Heparinized bone marrow cells were resuspended

in ~10 vol of erythrocyte-lysing buffer (155 mmol/L of NH₄Cl, 10 mmol/L of KHCO₃, and 2.5 mmol/L of EDTA, pH 7.3, 37°C) and immediately centrifuged. The marrow cells were resuspended and washed by centrifugation three times in PBS supplemented with 0.75% BSA and 2.5 mmol/L of EDTA. Washed marrow cells and MEG-01 cells were analyzed for the presence of vWf and protein S antigen in cytoplasm by an indirect immunofluorescent technique as described.⁹ Other human hematopoietic cell lines described above were also examined for the presence of cytoplasmic protein S.

RESULTS

Appearance of protein S in the culture medium. When 5×10^5 /mL of MEG-01 cells was subcultured in the new medium supplemented with 10% FCS, the concentration of protein S antigen in the medium increased progressively with time from <8 ng/mL on day 0 to 105.6 ± 6.0 ng/mL on day 13 (Fig 1). Each point in Fig 1 represents the mean $\pm$ SD of triplicate flasks. A similar increase was also found in the experiments using HB101 serum-free medium (data not shown). Cell lysates quantitatively analyzed for protein S antigen gave no evidence for a large intracellular pool of this protein. Immunoblot analysis of spent medium (day 2) revealed two distinct bands of mol wt ~84,000 and ~78,000 (Fig 2, lane 2) that are identical to the doublets of purified plasma protein S (lane 1). A faint band just below 78,000 band in lane 2 is probably a degradation product of protein S. In contrast, culture medium and cell lysates (day 5) of HL-60, K-562, MOLT 4 and U-937 cells contained no significant amount of protein S antigen (<2.5 ng/mL).

Fig 1. Time course of the accumulation of protein S antigen in the culture medium (A) and cell lysates (B) of MEG-01 cells. Three Falcon 3013 flasks were each seeded with 5×10^5 /mL MEG-01 cells in 8 mL of RPMI 1640 medium containing 10% fetal calf serum (FCS). On the days indicated, 1.8 mL of medium was removed and replaced with fresh medium. Antigen was measured using a specific enzyme-linked immunoassay (ELISA). The values are plotted as the mean $\pm$ SD. Line (C) shows the cell growth curve.

Fig 2. Immunoblot of purified protein S (lane 1) and day 3 culture medium (lane 2) shows the same doublets of mol wt 84,000 and 78,000. A faint band just below 78,000 is probably a degradation product of protein S.

Effect of vitamin K and warfarin. Because protein S is a vitamin K-dependent protein, the effects of vitamin K₂ and warfarin on the quantity and activity of secreted protein S by MEG-01 cells were examined. Vitamin K₂ (1 µg/mL) enhanced the accumulation of secreted protein S antigen in the medium, whereas warfarin (1 µg/mL) inhibited the secretion of this protein. Similar effects of vitamin K₂ and warfarin were also observed in the experiments with HB101 serum-free medium (data not shown).

Table 1. Effect of Vitamin K₂ and Warfarin on the Activity and Antigen of Secreted Protein S by MEG-01

	Protein S		Activity
	Antigen (ng/mL)	Activity (ng/mL)	Antigen
Fresh medium	5	0	0
Control culture	440	380	0.86
V-K ₂ in culture	680	750	1.10
Warfarin in culture	280	15	0.05

MEG-01 cells were seeded in Falcon 3013 flasks at 2×10^5 /mL in 40 mL of RPMI 1640 medium containing 10% fetal calf serum and cultured for 5 days with or without vitamin K₂ (1 µg/mL) and warfarin (1 µg/mL). Culture media, after 20-fold concentration, were assayed for protein S antigen and activity as described in the Materials and Methods section. Purified plasma protein S was used as a standard in both assays, and the results were expressed as nanogram of protein S per milliliter of 20-fold concentrated medium.

Fig 3. Time course of the accumulation of protein S antigen in the control culture medium (A), culture medium with 1 µg/mL of vitamin K₂ (B) and culture medium with 1 µg/mL of warfarin (C). MEG-01 cells were seeded at 2×10^5 /mL in 8 mL of RPMI 1640 medium containing 10% fetal calf serum (FCS). Values are expressed as nanogram of protein S antigen per milliliter of medium.

Table 1 shows the activity and antigen of secreted protein S when MEG-01 cells were cultured for 5 days in the absence or presence of vitamin K₂ and warfarin. As judged by the ratio (0.86) of activity/antigen, control MEG-01 cells appear to secrete fully functional protein S. Vitamin K₂ enhanced the secretion of functional protein S (activity/antigen: 1.10), whereas warfarin decreased both quantity and specific activity (0.05) of secreted protein S.

Incorporation of [³⁵S]-methionine into immunoprecipitable protein. To demonstrate de novo synthesis of protein S, we cultured the cells in the presence of [³⁵S]-methionine for 5 hours and immunoprecipitated the culture medium with anti-protein S serum. SDS-PAGE demonstrated a single band of mol wt ~84,000 (Fig 4, lane 1) that was absent in the control immunoprecipitates (Fig 4, lane 2). These data clearly indicate that MEG-01 cells synthesize and secrete protein S.

Immunofluorescence stainings. MEG-01 cells and bone marrow megakaryocytes showed positive granular staining patterns with anti-protein S serum (Figs 5 and 6). No other nucleated cells in bone marrow except megakaryocytes or HL-60, K 562, MOLT 4, and U-937 cells were positively stained. No positive staining was observed when MEG-01 cells and megakaryocytes were first reacted with normal rabbit serum and then with fluorescein isothiocyanate-conjugated second antibody. The pattern of staining of megakaryocytes or MEG-01 cells with anti-protein S serum was similar to that with anti-vWf serum, suggesting the presence of protein S in the cytoplasm of MEG-01 cells.

Fig 4. Autoradiogram of the immunoprecipitates from [^{35} S]-methionine-labeled proteins secreted from MEG-01 cells following incubation with normal rabbit serum (lane 2) and anti-protein S serum (lane 1).

Fig 5. Immunofluorescent staining of human megakaryocytes from bone marrow. Staining with anti-von Willebrand factor serum (A) reveals a granular staining pattern; staining with anti-protein S serum (B). (Original magnification $\times 400$.)

Fig 6. Immunofluorescent staining of MEG-01 cells. Staining with anti-von Willebrand factor serum (A); staining with anti-protein S serum (B). Granular staining pattern is observed in both photographs. (Original magnification $\times 1,000$; current magnification $\times 700$.)

Plasma protein S antigen in patients with aplastic anemia. The mean $\pm$ SD of protein S antigen in nine patients with untreated severe aplastic anemia was $26.9 \pm 2.8 \mu\text{g/mL}$, whereas that in 25 normal volunteers was $26.2 \pm 4.5 \mu\text{g/mL}$.

DISCUSSION

It was previously simply assumed that synthesis of vitamin K-dependent blood clotting factors was restricted to hepatocytes. Recent studies, however, have demonstrated that human monocyte-macrophage cells synthesize factor VII^{17,18} and that human and bovine endothelial cells produce protein S.^{4,5} Thus, other nonhepatocyte cells may also participate in the biosynthesis of some vitamin K-dependent coagulation proteins. Human platelets contain protein S,⁶ and the presence of this protein in human megakaryocytes and a human erythroleukemia cell line (HEL) has recently been reported.⁷ These studies suggested, but did not prove, that megakaryocytes may synthesize protein S.

In this report, we have provided definitive evidence for the production of functional protein S by human megakaryocytes. A human megakaryoblastic cell line (MEG-01) has

the capacity to synthesize and secrete functional protein S, which has a mol wt similar to that of the plasma form.¹⁹ Its synthesis can be affected by known pharmacologic modulators of vitamin K-dependent proteins. Protein S was detected in both MEG-01 cells and human megakaryocytes by indirect immunofluorescent technique. Although the immunohistochemical staining revealed protein S in the cytoplasm, MEG-01 cells appear to have a very small intracellular pool of this protein (Fig 1). MEG-01 cells are megakaryoblasts that lack α granules⁹; therefore, protein S synthesized by the cells may not be retained in the cytoplasm but rapidly secreted. β -Thromboglobulin, another platelet α -granule protein, was also synthesized and rapidly secreted as protein S (M.O., N.T., T.H., unpublished observations). Because MEG-01 cells are derived from blast crisis of chronic myelogenous leukemia (CML), it may be difficult to decide if the production of protein S by these cells reflects synthesis of normal megakaryocyte gene product or arises from gene depression due to transformation. MEG-01 cells, however, appear to retain the morphological features and the differentiated functions of normal megakaryoblasts.⁹ Leukemic buffy coat cells from a similar patient with accelerated phase of CML were also used as a model to demonstrate biosynthesis of von Willebrand protein by human megakaryocytes.²⁰

The observation that vitamin K₂ enhanced and warfarin inhibited the secretion of functional protein S by MEG-01 cells is similar to that of the secretion of protein S or

prothrombin by a human hepatoma cell line (Hep G2)^{3,21} or the protein S secretion by human and bovine endothelial cells.^{4,5} These results suggest that MEG-01 cells contain the enzymes required for γ -carboxylation.

Human platelets have been reported to contain 2.5% of protein S in whole blood.⁶ Because in the present study we found that megakaryocytes secrete protein S, we evaluated the contribution of megakaryocytes to the plasma level of this protein. Plasma protein S exists in two forms; free protein S and C4b-binding protein-protein S complex.²² The electroimmunoassay used in this study measures both free and complexed protein S (total protein S). There was no significant difference between the total protein S levels of small numbers of patients with severe aplastic anemia and those of normal controls. Thus, it is unlikely that protein S synthesized by megakaryocytes represents a main source of plasma protein S.

The present study adds protein S to a list of coagulation proteins such as vWf, factor V, and fibrinogen, which are synthesized by human megakaryocytes. The role of protein S produced by megakaryocyte in the local control of hemostasis and thrombosis remains to be investigated.

Detection of Activated Platelets in Whole Blood Using Activation-Dependent Monoclonal Antibodies and Flow Cytometry

By Sanford J. Shattil, Michael Cunningham, and James A. Hoxie

Platelets may become activated in a number of clinical disorders and participate in thrombus formation. We developed a direct test for activated platelets in whole blood using flow cytometry. Whole blood was incubated with either biotin-PAC1, a monoclonal antibody specific for the fibrinogen receptor on activated platelets, or biotin-S12, an antibody specific for an α -granule membrane protein that associates with the platelet surface during secretion. Platelet-bound antibodies were detected with streptavidin conjugated with fluorescein isothiocyanate (FITC) or phycoerythrin (PE). Platelets were differentiated from the larger erythrocytes and WBCs by their light-scatter profile. Alternatively, platelets could be identified with FITC-AP1, an antibody specific for platelet membrane glycoprotein Ib, and analyzed further for PAC1 or S12 binding with PE-streptavidin. No centrifugation or washing steps were required. With gel-filtered platelets, there was a direct correlation between ADP-induced biotin-PAC1 binding and binding determined in a conventional ^{125}I -PAC1 binding assay ($r = .99$; $P < .001$). Furthermore, as few as 0.8% activated platelets could be detected by flow cytometry

when activated platelets were mixed with unstimulated platelets. In whole blood, unstimulated platelets demonstrated no PAC1- or S12-specific fluorescence, indicating that they did not bind these antibodies. On stimulation with agonists, however, the platelets demonstrated a dose-dependent increase in fluorescence similar to that observed for platelets in plasma or buffer. Low concentrations of ADP and epinephrine, which induce fibrinogen receptors but little secretion, stimulated near-maximal PAC1 binding but little S12 binding. On the other hand, a concentration of phorbol myristate acetate (TPA) that evokes full platelet aggregation and secretion induced maximal PAC1 and S12 binding. Activated platelets could also be analyzed in whole blood samples that had been fixed with paraformaldehyde. These studies demonstrate that activated platelets can be reliably detected in whole blood using activation-dependent monoclonal antibodies and flow cytometry. This technique may be useful to assess the degree of platelet activation and the efficacy of antiplatelet therapy in clinical disorders.

CHANGES OCCUR at the platelet surface during cell activation. First, agonists bind to their membrane receptors and initiate the activation process. Then, for platelets to aggregate, heterodimer complexes of the membrane glycoproteins IIb and IIIa must be converted into competent receptors for fibrinogen.¹ During platelet secretion, granule membranes fuse with the plasma membrane or with membranes of the surface-connected open canalicular system.² The metabolic reactions responsible for these surface changes are only partly understood. In response to some agonists, such as thrombin, the exposure of fibrinogen receptors and the secretory response can occur as a result of agonist-induced phosphoinositide hydrolysis.³⁻⁸ On the other hand, weaker agonists such as epinephrine can stimulate fibrinogen receptor expression independent of phosphoinositide hydrolysis and cause secretion by stimulating arachidonic acid metabolism and thromboxane A_2 synthesis.⁹⁻¹¹

Recently, several murine monoclonal antibodies have been described that recognize antigenic determinants on the platelet surface, but only after platelet activation.^{9,12-14} For example, PAC1 is an IgM antibody that binds only to the activated form of the IIb-IIIa complex.⁹ It appears to recognize an epitope on the IIb-IIIa complex critical for fibrinogen binding. PAC1 and fibrinogen inhibit each other's binding in a competitive manner.^{9,15} Moreover, PAC1 binding is competitively inhibited by the tetrapeptide, Arg-Gly-Asp-Ser, which is present in the α chain of fibrinogen and functions as a cell attachment site for fibrinogen and other adhesive macromolecules.¹⁶ PAC1 has been useful in identifying the intracellular mediators responsible for fibrinogen receptor expression in activated platelets.³ Two other "activation-dependent" antibodies, S12 and KC4, recognize a 140-kd α -granule membrane protein that becomes associated with the platelet surface during secretion.^{12,13,17,18} Radiolabeled S12 has been used to detect activated platelets

in blood samples from patients with acute respiratory distress syndrome.¹⁹ Thus, activation-specific monoclonal antibodies may be useful both in unraveling the biochemical mechanisms of platelet activation and in detecting activated platelets in clinical disorders.

When platelets are stimulated to undergo a secretory response, they produce thromboxane A_2 and release the contents of their storage granules into the extracellular milieu. Some of these released substances, such as platelet factor 4 and β -thromboglobulin, are platelet-specific and can be detected in plasma by sensitive radioimmunoassays.²⁰ The measurement of these proteins in plasma and of thromboxane A_2 metabolites in plasma and urine has provided evidence for platelet activation in several clinical disorders.^{21,22} Although helpful in a research setting, these indirect methods have technical limitations that have precluded

their routine clinical use. For example, extreme care must be taken during blood sample collection and processing to prevent the *in vitro* release of platelet factor 4 and β -thromboglobulin.^{20,21}

The purpose of the present study was to develop a sensitive and specific direct assay for activated platelets in whole blood. To accomplish this, we used the activation-specific monoclonal antibodies, PAC1 and S12. The binding of these antibodies to platelets was detected using the sensitive technique of flow cytometry, which is capable of detecting and quantitating antigens on the surface of individual platelets.²³⁻²⁶

METHODS

Preparation of Monoclonal Antibodies

PAC1, an IgM murine monoclonal antibody specific for the activated form of the platelet membrane glycoprotein IIb-IIIa complex, and A₂A₆, an IgG antibody specific for the IIb-IIIa complex on resting or activated platelets, were purified as described previously.⁹ AP1, an IgG antibody specific for membrane glycoprotein Ib,²⁷ was kindly provided by Dr Thomas Kunicki, Blood Center of Southeastern Wisconsin, and purified by sequential precipitation of non-IgG proteins using rivanol and caprylic acid (T. Kunicki, personal communication). S12, an IgG antibody specific for a 140-kD α -granule membrane protein,^{13,18} was generously provided in pure form by Dr Rodger McEver, University of Texas at San Antonio. Antibody preparations were pure as judged by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Prior to their use in flow cytometry, these antibodies were conjugated either with biotin or with fluorescein isothiocyanate (FITC). Antibodies were biotinylated by incubating 500 μ g of antibody in 500 μ L of phosphate-buffered saline (PBS), pH 7.4, for 2 hours at room temperature with 50 μ L of 3.2 mmol/L of *N*-hydroxysuccinimide biotin ester in dimethyl sulfoxide and 50 μ L of 1 mol/L of NaHCO₃. The reaction was stopped with 50 μ L of 1 mol/L of NH₄Cl for 10 minutes, and the mixture was passed over a Sephadex G-25 column equilibrated with PBS. The biotinylated protein appeared in the void volume and was stored at 4°C until use. Antibodies were conjugated to FITC by first adjusting the pH of the antibody solution (1 mg/mL) to 8.5 to 9 with one-tenth vol of 1 mol/L of NaCO₃. Then, 1 mg of FITC-Celite (Calbiochem, San Diego) was added per milligram of antibody and the mixture was incubated for 10 minutes at room temperature with intermittent shaking. The sample was applied to a Sephadex G-25 column equilibrated with PBS, and FITC-conjugated antibody was recovered in the void volume. The fluorescein/protein molar ratio ranged between 3 and 4 for AP1 and S12 and 12 and 15 for PAC1. Biotin- and FITC-conjugated antibodies appeared to function normally in that their binding to platelets was saturable at antibody concentrations reported for the unconjugated species.^{9,13,27} In some experiments, PAC1 was radiolabeled with ¹²⁵I to compare the binding of the radiolabeled form of the antibody⁹ with that of the biotinylated form.

Preparation of Whole Blood Samples for Flow Cytometric Analysis

Blood was obtained from normal volunteers who had taken no medications for at least 10 days. In an attempt to minimize platelet activation during blood collection, the donor was supine, and blood was obtained from an antecubital vein through a 19-gauge butterfly needle with either a light tourniquet or no tourniquet. After the first

2 mL of blood were discarded, 4.5 mL of blood was collected into a plastic syringe containing 0.5 mL of 3.8% sodium citrate. In some experiments, the platelets were then fixed with 1% paraformaldehyde as described by George and colleagues.¹⁹ Within 1 minute of the collection of fresh blood or 45 minutes after platelet fixation, 5- μ L aliquots of the blood (containing 0.75 to 1.0 $\times$ 10⁶ platelets) were added to 12 $\times$ 75-mm polystyrene tubes containing 50 μ L of an isotonic HEPES buffer⁹ and 5 μ L of a saturating concentration of biotin-PAC1 (30 μ g/mL) or biotin-S12 (10 μ g/mL). In some experiments, platelets were activated by including 5 μ L of epinephrine, ADP, or phorbol myristate acetate (PMA) in the tubes. The samples were incubated at room temperature for 15 minutes without stirring. As described in detail below, platelets were analyzed by flow cytometry using either a single fluorochrome (the "one-color" method) or two fluorochromes (the "two-color" method). For the one-color method, after the incubation with the antibodies, a saturating concentration of FITC-streptavidin (5 μ L of a 1:10 dilution; Amersham, Arlington Heights, IL) was added, and the tubes were incubated for an additional 15 minutes. The samples were then diluted with 500 μ L of the isotonic buffer and analyzed. No washing steps were required. For the two-color method, one fluorescent reagent, FITC-AP1, was used to label and identify all the platelets while a second fluorescent reagent, phycoerythrin (PE)-streptavidin (Becton Dickinson, Mountain View, CA) was used to detect biotin-PAC1 or biotin-S12 bound to activated platelets. Specifically, after 15 minutes of incubation with the biotinylated antibody, 15 μ L of PE-streptavidin and 2 μ L FITC-AP1 was added for 15 minutes, and the sample was diluted and analyzed. In some studies, platelet-rich plasma (PRP) or gel-filtered platelets were prepared⁹ and then examined by flow cytometry as described above for whole blood.

Flow Cytometric Analysis

Blood samples were analyzed in a Becton Dickinson FACStar flow cytometer. The instrument was equipped with a 5 W argon laser and operated at 200 mW power at a wave length of 488 nm. Fluorescein fluorescence was detected using a 530/30 band pass filter, and PE fluorescence was detected with a 585/42 filter. The instrument was calibrated for fluorescence and light scatter daily using 2- μ m Calibrite beads (Becton Dickinson). Blood samples were passed through the laser beam through a 70- μ m nozzle at a flow rate of 10,000 blood cells per second. Light scatter and fluorescence data were obtained with gain settings in the logarithmic mode, and the data were analyzed on a Hewlett-Packard Consort 30 H-P 217 computer (Palo Alto, CA).

For one-color analysis, the platelets were distinguished from erythrocytes and WBCs on the basis of their forward- and side-light scatter profile (described in the Results section). Debris or "machine noise" demonstrated a scatter profile distinctly smaller than that of platelets and was excluded from the analysis by setting the appropriate forward-scatter threshold. A gate was set around the platelets, and 10,000 cells were analyzed for FITC fluorescence to quantitate the amount of platelet-bound PAC1 or S12. Antibody binding was expressed either as the mean fluorescence intensity or as the percentage of platelets positive for antibody. Antibody-positive cells were defined as those platelets with a fluorescence intensity >99.0% to 99.5% of unstimulated platelets that had been prepared in the presence of 1 μ mol/L of PGI₂.

For two-color analysis, a fluorescence threshold was set to analyze only those blood cells that had bound FITC-AP1. Because erythrocytes and WBCs do not bind this platelet-specific antibody, they were effectively excluded from the analysis. Platelet-bound biotin-PAC1 or S12 was then determined by analyzing 10,000 platelets for PE-streptavidin fluorescence.

RESULTS

Detection of Activated Gel-Filtered Platelets With Monoclonal Antibodies

To explore the feasibility of using activation-dependent monoclonal antibodies to detect activated platelets by flow cytometry, initial studies were performed with gel-filtered platelets. For these studies, the one-color method of flow cytometric analysis, described in the Materials and Methods section, was used. The binding of biotin-PAC1 as assessed by flow cytometry was compared with the binding of ^{125} I-PAC1 determined in a standard filtration binding assay. Gel-filtered platelets were incubated with PGI_2 to prevent platelet activation or were stimulated with concentrations of ADP ranging from 0.01 to 5 $\mu\text{mol/L}$. Whether biotin-PAC1 binding was expressed as mean fluorescence intensity or as the percentage of platelets binding PAC1, there was a high correlation between binding detected by flow cytometry and that detected with ^{125} I-PAC1 ($r = .99$; $P < .001$) (Fig 1). An advantage of flow cytometry over conventional binding assays is its ability to detect heterogeneity in platelet responsiveness to agonists. When platelets were incubated with biotin-PAC1 in the presence of 0.4 $\mu\text{mol/L}$ of ADP, only a portion of the platelets demonstrated fluorescence above baseline (Fig 2). With a higher concentration of ADP (4 $\mu\text{mol/L}$), an increasing percentage of the platelets demonstrated positive fluorescence, although these cells varied greatly in the extent to which they had bound PAC1. At an even higher concentration of ADP (40 $\mu\text{mol/L}$), most platelets had bound maximal or near-maximal amounts of PAC1.

To see if flow cytometry could detect minor degrees of platelet activation, platelets were activated with 20 $\mu\text{mol/L}$ of ADP and epinephrine and labeled with biotin-PAC1. These platelets were then mixed with various amounts of unactivated platelets that had been labeled with PAC1 in the presence of PGI_2 . Even when the final platelet mixture

Fig 2. Identification of subpopulations of activated platelets by flow cytometry. Gel-filtered platelets were incubated for 15 minutes with biotin-PAC1 in the presence of no ADP (A), 0.4 $\mu\text{mol/L}$ of ADP (B), 4 $\mu\text{mol/L}$ of ADP (C) or 40 $\mu\text{mol/L}$ of ADP (D). Then FITC-streptavidin was added, and the cells were analyzed for PAC1 binding by flow cytometry.

contained as few as 0.8% activated platelets, these could still be detected and differentiated from a control sample containing only unactivated platelets (Fig 3).

Fibrinogen is a competitive inhibitor of PAC1 binding to platelets.^{9,15} Because this is a potential problem with whole blood, in which plasma fibrinogen is present in large amounts, biotin-PAC1 binding to platelets was compared in plasma and buffer. When a saturating concentration of PAC1 was added simultaneously with an agonist such as ADP or phorbol ester, there was no difference in PAC1 binding between PRP and gel-filtered platelets over a range of agonist concentrations (not shown). This may be due to

Fig 1. Relationship between biotin-PAC1 binding and ^{125} I-PAC1 binding to ADP-stimulated platelets. Gel-filtered platelets were incubated either with 1 $\mu\text{mol/L}$ PGI_2 to prevent platelet activation, or stimulated for 1 minute with various concentrations of ADP ranging from 0.01 to 5.0 $\mu\text{mol/L}$. They were then incubated with ^{125} I-PAC1 (18 $\mu\text{g/mL}$), and the amount of PAC1 bound to the platelets was determined. In parallel, the platelets were incubated with biotin-PAC1, and PAC1 binding was quantitated by flow cytometry. Biotin-PAC1 binding was expressed either as the mean fluorescence intensity of stimulated platelets relative to PGI_2 -treated platelets (left panel) or as the percentage of cells exhibiting positive fluorescence (right panel). Data represent the mean of two experiments.

Fig 3. Detection of activated platelets when mixed with unstimulated platelets. Gel-filtered platelets were stimulated with a combination of 20 $\mu\text{mol/L}$ of ADP and epinephrine and then incubated with biotin-PAC1. The sample contained an average of 85% PAC1-positive platelets. Small but increasing amounts of the sample were then added to a sample of unstimulated, PGI_2 -treated platelets, and the final mixtures were analyzed for PAC1 binding by flow cytometry. The scale on the ordinate ranges from 0% to 10% positive platelets. All mixtures containing stimulated platelets showed more PAC1-positive cells than did the PGI_2 control ($P \leq .01$). Data represent the mean $\pm$ SEM of four experiments.

the greater apparent affinity of PAC1 ($K_d = 5 \text{ nmol/L}$) than fibrinogen ($K_d = 250 \text{ nmol/L}$) for the fibrinogen receptor.^{9,15} Another potential confounding effect of fibrinogen in whole blood assays is that the binding of this ligand is initially reversible but becomes progressively irreversible over the course of 60 minutes.¹ Indeed, when biotin-PAC1 was added to PRP after stimulation of the platelets with an agonist, there was a time-dependent reduction in the mean fluorescence intensity of PAC1-positive cells, suggesting that fibrinogen had become irreversibly bound to a portion of the fibrinogen receptors (Fig 4). Despite this, there was no reduction in the percentage of platelets binding PAC1. This suggests that with sustained platelet activation, fibrinogen had become irreversibly bound to a fraction of the fibrinogen receptors on each platelet (Fig 4).

Detection of Activated Platelets in Whole Blood With Monoclonal Antibodies

Flow cytometric analysis of whole blood using the one-color method. Having demonstrated the feasibility of using PAC1 to detect activated platelets after gel filtration, we asked whether similar studies could be carried out in whole blood. To be successful, whole blood analysis would have to include all platelets but exclude all erythrocytes and WBCs. Two different methods were evaluated to accomplish this. In the one-color method, platelets were identified on the basis of their light-scatter profile (Fig 5A). The forward- and side-scatter profiles of platelets could be clearly separated from the larger erythrocytes and WBCs, and a gate could be set around the platelets for analysis. The light-scatter profile of platelets was not affected by the presence of platelet agonists. Studies with gel-filtered platelets and washed erythrocytes confirmed their separation by this method. Approximately 0.5% of gel-filtered platelets appeared outside the platelet

Fig 4. Effect of duration of platelet activation on subsequent binding of biotin-PAC1 to platelets in plasma. Platelet-rich plasma was incubated with 0.2 $\mu\text{mol/L}$ of phorbol myristate acetate (TPA). At the indicated times, biotin-PAC1 was added to the sample, and PAC1 binding was determined by one-color flow cytometry. The percentage of PAC1-positive cells was not affected by the prolonged incubation of activated platelets with fibrinogen, whereas the amount of PAC1 bound per cell (mean fluorescence intensity) did decrease with time.

gate, whereas no more than 0.3% of erythrocytes appeared inside this gate. Thus, assuming a ratio of 20:1 of erythrocytes to platelets in whole blood, at most only 6% of the particles in the platelet gate could have been accounted for by erythrocytes. This agrees well with the observation that ~95% of the cells from whole blood appearing within the platelet gate bound biotin-AP1 or biotin-A2A9, antibodies specific for platelet membrane glycoproteins Ib and IIb-IIIa, respectively.^{27,28} In the experiment shown in Fig 5B, platelets in whole blood were stimulated with ADP and epinephrine in the presence of biotin-PAC1. Following the addition of FITC-streptavidin, the fluorescence of these platelets was compared with that of platelets incubated with PGI_2 to prevent activation. Resting platelets demonstrated minimal fluorescence, similar to control platelets that had not been incubated with antibody. In contrast, platelets stimulated with ADP and epinephrine demonstrated a marked increase in fluorescence.

Flow cytometric analysis of whole blood using the two-color method. Although significant overlap of the platelets with erythrocytes was not a problem in the one-color studies, such overlap may conceivably exist when a different flow cytometer is used or if blood cell light-scatter profiles are abnormal in disease states. Therefore, we evaluated a different approach in which a fluorescent platelet-specific marker, FITC-AP1, was used to identify the platelets in whole blood. Whole blood was incubated first with biotin-PAC1 and then with PE-streptavidin and FITC-AP1. Having bound FITC-AP1, the platelets now exhibited a strong green fluorescence. The machine threshold was then set to exclude from analysis cells that did not exhibit this degree of

Fig 5. Example of the one-color method of flow cytometric analysis of activated platelets. As described in the Materials and Methods Section, 5 μ L of whole blood were incubated with biotin-PAC1 and with either 1 μ mol/L of PGI₂ to maintain the platelets in a resting state or with 20 μ mol/L of ADP plus epinephrine to expose fibrinogen receptors. Then FITC-streptavidin was added, and the sample was analyzed by flow cytometry. The light scatter data are depicted over 4 log decades (A). The platelets appeared to be separated from erythrocytes and WBCs on the basis of their forward- and side-light scatter, and a gate was placed around the platelets for analysis. For each sample, the cytometer analyzed 10,000 cells within the platelet gate; a histogram of FITC ("green") fluorescence of these cells is shown (B).

green fluorescence (erythrocytes and WBCs), and the platelets were analyzed for biotin-PAC1 binding with PE-streptavidin. Preliminary studies showed that the binding of PAC1 or S12 to platelets did not affect the binding of AP1, nor did AP1 interfere with the binding of the other antibodies. The light-scatter profile for AP1-positive platelets in whole blood showed that ~95% of the cells were in an area expected for single platelets, whereas 5% of the cells demonstrated increased forward- and side-light scatter (Fig 6A).

Separate studies using isolated WBCs and leukocyte-specific antibodies demonstrated that this latter area also contained granulocytes and monocytes (not shown). Thus, since AP1 does not bind to WBCs, this minor population of AP1-positive cells probably represents platelets associated with WBCs. It is unlikely that this population represents platelet aggregates since we found no increase in the percentage of platelets in this scatter area when either platelets in whole blood or gel-filtered platelets were stimulated with agonists.

Fig 6. Example of the two-color method of flow cytometric analysis of activated platelets. Whole blood was incubated with biotin-PAC1 and either PGI₂ or ADP plus epinephrine. Then phycoerythrin-streptavidin and FITC-AP1 were added, and the samples were analyzed by flow cytometry. Light-scatter profile of AP1-positive cells (A). These platelets exhibited two separate light-scatter populations. About 95% of the cells appeared to be single platelets, whereas 5% of the platelets exhibited greater light scatter. Once the platelets were identified by their AP1 binding, biotin-PAC1 binding was quantitated by analyzing the platelets for phycoerythrin ("red") fluorescence (B).

When the AP1-positive cells were analyzed for biotin-PAC1 binding, activated platelets showed increased PE fluorescence (Fig 6B). There was no difference in the degree of PAC1 binding between platelets in the major and minor light-scatter profiles. On the other hand, platelet stimulation with epinephrine, ADP, or phorbol ester did not cause significant changes in AP1 binding. In the present studies, the one-color and two-color methods of platelet analysis yielded similar results. Therefore, in the experiments presented below, these methods were used interchangeably.

Effect of platelet agonists on PAC1 and S12 binding. When whole blood was incubated with platelet agonists, the binding of biotin-PAC1 was dependent on the concentration of the agonist (Fig 7). Dose-response curves for epinephrine, ADP, and TPA in whole blood were essentially identical to the corresponding dose-response curves for platelets in plasma or buffer. Moreover, PAC1 binding in response to a submaximal concentration of ADP was augmented by the addition of a low concentration of epinephrine (Fig 7).

S12 is an antibody that recognizes a 140-kd α -granule membrane protein which fuses with the platelet plasma membrane during secretion.^{13,18} The binding of saturating concentrations of biotin-S12 was compared with the binding of biotin-PAC1 to platelets in whole blood. Platelets activated with ADP or ADP plus epinephrine demonstrated binding of both antibodies. At a given concentration of agonist, however, there was more PAC1 than S12 binding (Fig 8). This was expected because unstirred platelets stimulated with weak agonists undergo minimal secretion yet are capable of expressing most of their fibrinogen receptors.⁹ In contrast, platelets stimulated maximally with TPA bound maximal amounts of PAC1 and S12 (Fig 8).

Stability of platelets in whole blood. The above studies were carried out using whole blood that had been processed

Fig 7. Effect of agonists on the binding of biotin-PAC1 to platelets in whole blood. Whole blood was incubated with the indicated concentrations of agonists and biotin-PAC1. Then PE-streptavidin and FITC-AP1 were added, and the platelets were analyzed for PAC1 binding by the two-color flow cytometry method. The experiment is representative of three so performed. TPA refers to phorbol myristate acetate.

Fig 8. Comparison of the binding of the monoclonal antibodies, PAC1 and S12, to platelets in whole blood. Whole blood was incubated with various agonists and either biotin-PAC1 (open symbols) or biotin-S12 (closed symbols). The samples were then analyzed by one-color flow cytometry, and the amount of antibody bound to the platelets was determined. The experiment is representative of three so performed.

within 1 minute of venipuncture. If the testing of clinical samples is to become feasible, however, it is essential that platelets not become activated spontaneously before analysis. Therefore, we examined the stability of both resting and stimulated platelets during longer periods of incubation. Whole blood containing 0.38% sodium citrate was placed in a capped polypropylene tube. At various times up to 60 minutes aliquots of the blood were incubated with biotin-PAC1 or biotin S12 and then evaluated by flow cytometry. If the blood was allowed to stand for >10 minutes before the addition of antibody, there was a small but perceptible increase in the percentage of platelets binding either PAC1 or S12 (Fig 9). Once either antibody was added to resting or stimulated platelets, however, the platelets maintained their initial degree of platelet activation for up to 2 hours (not shown). Thus, if unfixed blood is to be analyzed and spontaneous platelet activation avoided, the blood specimen should be processed within 10 minutes and analyzed within 2 hours of collection.

It may be necessary to study blood samples from patients hours or days after blood collection. Therefore, the effect of fixing whole blood with 1% paraformaldehyde was examined. Whole blood was fixed as described by George and colleagues,¹⁹ either within seconds of venipuncture or 15 minutes after activation with phorbol ester. Then biotin-PAC1 or S12 was added. Although fixation of blood before the addition of the antibodies was successful in preventing the small time-dependent spontaneous activation of platelets that had been observed with unstimulated and fixed platelets, this procedure resulted in a significant reduction in PAC1 and S12 binding to stimulated cells (Fig 10). In contrast, when the blood was sequentially stimulated with an agonist, incubated with the antibodies and then fixed, PAC1 and S12 binding was similar to that observed for binding to stimulated, unfixed platelets (Fig 10). Furthermore, the amount of antibody bound to platelets fixed after antibody addition was stable for at least 24 hours. Similar results with

Fig 9. Effect of incubation time on the spontaneous activation of platelets in whole blood. Whole blood anticoagulated with 0.38% sodium citrate was either processed immediately for flow cytometry or allowed to stand in a capped polypropylene tube at room temperature for periods of 0 up to 60 minutes. At the indicated times, aliquots of blood were incubated with saturating concentrations of biotin-PAC1 (A) or biotin-S12 (B), and antibody binding was determined by two-color flow cytometry. The scale on the ordinates range from 0% to only 2% positive platelets. The *P* values compare the data at each time point with that obtained at zero time on platelets incubated with PGI₂ (solid bars). The data represent the mean $\pm$ SEM of platelets from ten normal donors.

fixed platelets were obtained when the antibodies were conjugated with FITC instead of biotin.

DISCUSSION

To function during hemostasis, platelets must become activated. Platelets may also become activated in certain pathologic conditions and participate in the process of thrombogenesis.^{21,22} In the present studies, we sought to develop a direct method to detect activated platelets in whole blood specimens immediately after venipuncture and without the need to centrifuge or wash the specimen. We took advantage of the availability of PAC1 and S12, two monoclonal antibodies that bind specifically to activated but not to resting platelets. PAC1 detects a change in the glycoprotein IIb-IIIa complex occurring during platelet activation that converts the complex into a competent fibrinogen receptor.⁹ S12 detects an α -granule membrane protein that becomes exposed on the platelet surface coincident with granule secretion.^{13,18} The binding of these antibodies to activated platelets was detected by flow cytometry. The antibodies were conjugated with biotin, and binding was detected with streptavidin conjugated either with fluorescein or PE. Plate-

Fig 10. Effect of fixation with 1% paraformaldehyde on PAC1 and S12 binding to platelets in whole blood. Whole blood was incubated for 15 minutes with either biotin-PAC1 or biotin-S12; then FITC-streptavidin was added, and the amount of antibody bound to the platelets was determined by one-color flow cytometry. Open bars represent platelets from unfixed blood incubated with PGI₂ during the antibody and FITC-streptavidin steps. Closed bars represent platelets from unfixed blood stimulated with 0.2 μ mol/L of phorbol myristate acetate for 15 minutes during the incubation with antibody. Striped bars represent platelets from blood stimulated with the phorbol ester for 15 minutes and then fixed with paraformaldehyde before the antibody incubation steps. Stippled bars are platelets from blood that was stimulated with 0.2 μ mol/L of phorbol myristate acetate and fixed after the incubations with antibody and FITC-streptavidin. Data represent the mean $\pm$ SEM of seven experiments.

lets activated with agonists *in vitro* bound the fluorescently tagged antibodies and were distinguishable from resting platelets on the basis of their fluorescence intensity. The amount of platelet-bound antibody measured by flow cytometry correlated strongly with the amount of bound ¹²⁵I-antibody measured in a standard filtration assay. Antibody binding to platelets in whole blood was dependent on the agonist concentration, and the dose-response curves were similar to those for platelets in plasma or buffer. Furthermore, mixing studies showed that if as little as 0.8% activated platelets was present in the platelet sample, they could be detected by flow cytometry. Thus, the method described appears to be a sensitive and direct one for the detection of activated platelets.

Precise analysis of platelets in whole blood requires that these cells be clearly differentiated from erythrocytes and WBCs by the flow cytometer. Two different protocols were established for this purpose. In the one-color method, platelets were identified by their light-scatter profile. Under the conditions used, there was minimal overlap between platelets and the larger blood cells so that only ~5% of the cells in the platelet scatter area could be accounted for by erythrocytes. Therefore, for platelet analysis, a gate was set around this scatter area, and antibody binding was determined by quantitating platelet fluorescence. When platelets were stimulated by an agonist but not stirred, the activated platelets exhibited the same forward- and side-scatter profiles as

resting platelets. Although the one-color method was acceptable for the present studies, it has potential disadvantages. First, it may not be possible to so clearly differentiate platelets from erythrocytes on the basis of light scatter using other flow cytometers.²⁵ Second, blood in this study was obtained from normal volunteers. Platelets may show more light scatter overlap with erythrocytes in certain disease states. Third, we found that ~5% of the platelets in whole blood demonstrated a light-scatter profile similar to that of WBCs, consistent with the report of Jennings and colleagues that platelets can be loosely associated with granulocytes or monocytes.²⁵ This minor population of platelets would not be analyzed by the one-color method. Although the percentage of platelets apparently associated with WBCs did not change with platelet activation, this may not be the case in disease states. To overcome these potential drawbacks, we evaluated a different two-color method of analysis that did not depend on light scatter to identify platelets.

In the two-color method, platelets were labeled with biotin-PAC1 or S12 and then identified with the platelet-specific antibody, FITC-API, which recognizes platelet membrane glycoprotein Ib. The cytometer threshold was set to analyze only FITC-API-positive cells, thereby eliminating erythrocytes and WBCs from the analysis. Biotin-PAC1 or S12 binding was then detected with PE-streptavidin, and activated platelets were identified by their PE fluorescence. When using this method to differentiate platelets from other blood cells, it is important to use an antibody to detect platelets whose binding does not change significantly with platelet activation. Although API binding decreases during thrombin-induced platelet activation,^{29,30} we did not observe sufficient changes in API binding with ADP, epinephrine, or phorbol ester to preclude its use as a platelet marker for two-color analysis.

Several variations of this two-color method could increase its range of usefulness for specific applications. For example, the activation-dependent antibodies can be directly labeled with FITC, and the API could be labeled with biotin. Indeed, S12 has been simultaneously labeled with FITC and ¹²⁵I to correlate directly the antibody binding observed in flow cytometric and radioisotopic assays.²⁶ It should also be possible to label PAC1 with FITC and S12 with biotin and evaluate the binding of these two activation-dependent antibodies simultaneously.

Whole blood flow cytometry for the study of activated platelets has several advantages. First, only microliter volumes of blood are required, making it possible to study infants or individuals with thrombocytopenia. Second, as illustrated in Fig 5, platelet subpopulations that are heterogeneous in their platelet response to stimulation can be detected, which is not possible with methods that rely on ¹²⁵I-antibody binding or on measurements of released platelet factor 4 or β -thromboglobulin. Third, the use of whole blood eliminates the need for centrifugation or washing. These procedures can result in platelet activation. No method of *ex vivo* analysis, however, will prevent activation of platelets that may take place during a traumatic or prolonged venipuncture. Thus, close attention must be paid to the details of venipuncture. In this study, we attempted to minimize acti-

vation by drawing blood from the antecubital vein with the subject supine, using little or no tourniquet, and discarding the initial 2 mL of blood.

The stability of platelets *in vitro* is a major variable in these types of studies. We found that spontaneous activation of platelets did not occur if PAC1 or S12 was added to the blood sample within 10 minutes of venipuncture. A small but detectable increase in PAC1 or S12 binding was observed, however, if blood was allowed to stand for longer periods of time before the addition of antibody. Therefore, if a direct assay for activated platelets is to gain wider use, it may be desirable to fix the blood sample after venipuncture. Fixation of the blood with 1% paraformaldehyde immediately after venipuncture prevented spontaneous platelet activation. If platelets were stimulated with an agonist and then fixed, however, antibody binding to the fixed platelets was significantly reduced as compared with unfixed platelets. This problem was circumvented by adding the paraformaldehyde *after* the antibody. The effects of platelet fixation for each antibody used must be carefully evaluated.

Whether the direct analysis of platelets will be useful in detecting and quantitating the degree of platelet activation in clinical disorders remains to be established. Based on studies with plasma platelet factor 4, β -thromboglobulin, and the plasma and urinary metabolites of thromboxane A₂, it appears that platelet activation can accompany unstable angina, adult respiratory distress syndrome, cardiopulmonary bypass, and renal dialysis.^{21,22,31,32} In addition, it is conceivable that activated platelets circulate in other disorders, such as thrombotic thrombocytopenic purpura. Even if a fraction of the platelets activated in these conditions continued to circulate in the blood, they might be detectable using activation-dependent monoclonal antibodies. Indeed, George and co-workers, using ¹²⁵I-S12, found activated platelets in 46% of patients with adult respiratory distress syndrome but in only 11% of patients undergoing cardiopulmonary bypass.¹⁹ Although this may indicate that the mechanism of platelet activation varies in different clinical disorders, the results may also be accounted for by the detection limits of the assay. The present studies suggest that assay sensitivity may be increased by using flow cytometry rather than conventional radioligand binding methods and by using a panel of activation-dependent monoclonal antibodies. Nonetheless, careful studies will be required to establish the sensitivity and specificity of the flow cytometry technique and its clinical value in detecting activated platelets in humans.

ACKNOWLEDGMENT

We are most grateful to Drs Thomas Kunicki and Rodger McEver for supplying monoclonal antibodies and to Dr Virgil Woods for his advice on labeling antibodies with biotin and FITC.

CONCISE REPORT

Physiologic Regulation and Tissue Localization of Renal Erythropoietin Messenger RNA

By Stephen J. Schuster, Jean H. Wilson, Allan J. Erslev, and Jaime Caro

Although erythropoietin (Epo) is produced primarily by the kidneys in response to hypoxia, the precise cell type(s) and mechanisms by which these cells regulate production are poorly understood. In the experiments we report, the kinetics of renal Epo production in response to acute hypoxia and the intrarenal localization of cellular Epo synthesis were studied at the level of Epo mRNA. Erythropoietin mRNA expression was determined by Northern blot analysis of rat kidney RNAs using a probe derived from the mouse Epo gene. Renal Epo mRNA content increased as early as 1 hour after initiation of hypoxia and continued to accumulate during 4 hours of stimulation. Discontinuation of the hypoxic stimulus resulted in rapid decay of mRNA

levels. Kidney and plasma Epo levels measured by radioimmunoassay paralleled, with respective lag times, the changes in renal Epo mRNA content, suggesting that Epo production in response to acute hypoxia represents de novo synthesis and is regulated by changes in Epo mRNA. Northern blot analysis of RNAs extracted from separated glomerular and tubular tissue fractions revealed Epo mRNA in the tubular fraction, whereas glomerular tissue did not contain Epo mRNA. Thus, the site of cellular Epo synthesis is located in the renal tubule or its interstitium and not in the glomerular tuft.

© 1987 by Grune & Stratton, Inc.

THE GLYCOPROTEIN growth factor erythropoietin (Epo) is produced primarily by the kidneys¹ and stimulates proliferation and differentiation of erythroid progenitor cells in the bone marrow.² The plasma Epo level increases in response to hypoxia and thus regulates production of mature, oxygen carrying RBCs to meet tissue requirements. Recently, Epo mRNA was shown to accumulate within the kidney in response to acute anemia³ and cobalt exposure.⁴ However, the kinetics of Epo mRNA changes in response to hypoxic hypoxemia and the precise cellular localization of Epo production within the kidney remain unknown. A glomerular origin of renal Epo has been suggested by immunofluorescence studies⁵ and by reports of Epo production by in vitro glomerular⁶ and mesangial cell⁷ cultures. In contrast, the greater intracellular Epo content in tubular tissue⁸ and in vitro Epo production by a proximal tubular cell line⁹ support a tubular cell site of renal Epo synthesis. In this report, we describe the kinetics of renal Epo mRNA expression in response to acute hypoxia and relate this to renal Epo production. Furthermore, we localize Epo mRNA within the kidney to the nonglomerular tissue.

MATERIALS AND METHODS

For the kinetic studies, adult male Wistar rats were placed in a hypobaric chamber at 0.4 atmosphere, and kidneys were obtained

from groups of animals removed at 1, 2, and 4 hours after the onset of hypoxia. After 4 hours of hypobaric hypoxia, kidneys were obtained from groups of rats kept at normobaric conditions for 1, 2, and 3 hours posthypoxia. PolyA⁺ RNA was prepared from whole kidney homogenates in each experimental group and Northern blot analysis was performed as described below. Epo content of kidney extracts and plasma for each experimental group was determined by radioimmunoassay as previously described.⁸

Localization of Epo mRNA within specific kidney tissue fractions was studied in animals whose Epo production had been maximally stimulated by combining exposure to hypoxia and cobalt. Kidneys were obtained from animals injected with cobalt chloride (6 mg/100 g of weight) and exposed 12 hours later to 4 hours of hypobaric hypoxia at 0.4 atmosphere. The cortical tissue was separated into glomerular and tubular fractions using a differential sieving technique as previously described.⁸ The first fraction consisted of a mixture of intact and decapsulated glomeruli as verified by phase and electron microscopy studies. The second fraction consisted of intact tubular fragments and single tubular cells with a small amount of interstitial cell contamination. The tubular origin of this fraction was confirmed by histologic studies and by measurement of specific brush border membrane enzymes.¹⁰ PolyA⁺ RNA was extracted from both fractions as well as from stimulated and control whole kidneys, and Northern blot analysis was performed.

Total RNA was extracted from whole kidney homogenates and kidney tissue fractions using the guanidinium-cesium chloride technique,¹¹ and polyA⁺ RNA was selected using oligo(dT)-cellulose chromatography.¹² PolyA⁺ RNA samples (10 µg) were denatured in formamide-formaldehyde and electrophoresed in a 1.4% formaldehyde/agarose gel as described.¹² RNAs were then transferred to a Nytran membrane (Schleicher and Schuell) in 10× standard saline citrate (SSC) and hybridized with a complementary strand RNA probe for Epo mRNA. The Epo probe was derived from a 660-base pair (bp), *SmaI-EcoRI* fragment of the mouse Epo gene inserted into a pSP65 plasmid. This genomic fragment represents 160 bases of intron IV and 500 bases of exon V.^{13,14} Complementary strand RNA probes were generated by in vitro transcription by SP6 RNA polymerase of the coding strand of the insert, using ³²P-cytidine triphosphate as previously described,¹⁵ and yielded RNA probes with specific activity of 10⁸ cpm/µg. Northern blots were hybridized at 65°C with probe (10⁷ cpm/mL) in 50% formamide, 10% dextran sulfate (wt/vol), 20 mmol/L of NaPO₄, pH 6.5, 5× SSC, 0.2% sodium dodecyl sulfate (SDS), 0.05% bovine serum albumin (BSA), 0.05% Ficoll, 0.05% polyvinylpyrrolidone (PVP), 200 µg/mL of denatured salmon sperm DNA, 1 mg/mL yeast tRNA, and 100

$\mu\text{g/mL}$ each of poly A, poly I, and poly C. After hybridization for 12 hours, nylon filters were washed under progressively more stringent conditions with final wash in $0.1 \times \text{SSC}$, 0.1% SDS at 65°C . Washed filters were further digested with RNase A¹⁶ and exposed for 12 to 24 hours to Kodak XAR-5 film at -70°C using intensifying screens.

Control Northern blots were hybridized with a mouse glyceraldehyde-3-phosphate dehydrogenase cDNA probe labeled by nick-translation to a specific activity 10^8 cpm/ μg of DNA using ^{32}P -deoxycytidine triphosphate.¹⁷ Hybridization conditions were similar to those described above except that hybridization and stringency washing were at 42°C . Northern blots hybridized with nick-translated probe were not digested with RNase A following stringency washes.

RESULTS

To study the kinetics of Epo mRNA expression, polyA⁺ RNA was extracted from whole rat kidney homogenates at various times during a 4-hour hypoxic challenge and at various intervals posthypoxia. The analysis of Northern blots (Fig 1) revealed Epo mRNA as early as 1 hour after initiation of hypoxia with progressive accumulation during 4 hours of observation. During the posthypoxic state, there was a sharp decline in mRNA with 50% of the signal lost in the first hour and none detectable 3 hours after discontinuation of the stimulus. The observed signal for Epo mRNA originated at 1.8 kilobases (kb), which is consistent with the size previously reported by Beru and colleagues.⁴

To relate Epo mRNA levels with changes in protein production, measurements of the change in the Epo content of the kidney and plasma were made in similarly treated groups of animals using a sensitive Epo radioimmunoassay.⁸ As shown in Fig 2, the intrarenal level of Epo starts to change after 1 hour of hypoxia, reaching its peak after 4 hours of stimulation. During the posthypoxic period, there is a rapid decline in renal Epo. The plasma levels of the hormone

Fig 1. Northern blot analysis of RNA from rat kidneys obtained at various times after the onset of hypoxia and during the posthypoxic period. PolyA⁺ RNAs were prepared for each time point and hybridized with a complementary strand RNA probe for erythropoietin (Epo) mRNA.

Fig 2. Changes in plasma and kidney erythropoietin (Epo) content in rats at various times after onset of hypoxia and during the posthypoxic period. Experimental design was the same as in Fig 1. Epo levels in plasma and kidney homogenates were measured by a sensitive radioimmunoassay as previously described.⁸ Results are expressed as the mean $\pm$ SE of two or three independent measurements.

parallel, with a short lag time, the changes seen in kidney Epo content and Epo mRNA.

To localize cellular Epo synthesis within the kidney, kidneys from stimulated rats were separated into glomerular and tubular tissue components, and tissue fractions were probed independently for Epo mRNA content. Northern blot analysis (Fig 3A) showed an intense signal in stimulated whole kidney and in the corresponding tubular fraction RNA, whereas no signal was detected in glomerular fraction RNA. The difference in intensity of signal between total kidney and tubular fraction RNAs can be explained in part

Fig 3. Localization of erythropoietin (Epo) mRNA in whole kidneys and separated kidney tissue fractions. Kidneys were obtained from hypoxic animals and separated by a sieving technique into the glomerular and tubular fractions.⁸ PolyA⁺ RNA was extracted, and northern blot analysis was performed as described. Hybridization with ^{32}P -labeled Epo RNA probe (A). Lane 1, stimulated whole kidney ($10 \mu\text{g}$); lane 2, stimulated tubular fraction ($20 \mu\text{g}$); lane 3, stimulated glomerular fraction ($20 \mu\text{g}$); and lane 4, normal whole kidney ($10 \mu\text{g}$). Hybridization with ^{32}P -labeled nick-translated¹⁷ glyceraldehyde-3-phosphate dehydrogenase cDNA probe (B). Lane 1, stimulated whole kidney ($10 \mu\text{g}$); lane 2, stimulated tubular fraction ($10 \mu\text{g}$); and lane 3, stimulated glomeruli ($10 \mu\text{g}$).

by the short half-life of the mRNA, since the separation procedure takes ~30 minutes. Quantitation of mRNAs in the different fractions was verified by hybridization with a ³²P-labeled glyceraldehyde-3-phosphate dehydrogenase cDNA probe, as shown in Fig 3B.

In whole kidney and tubular fraction RNAs, there appeared to be significantly more degradation of the Epo mRNA as compared with glyceraldehyde-3-phosphate dehydrogenase message. Technical factors may have contributed to this appearance, however, since the autoradiographs probed for Epo mRNA were intentionally overexposed to enhance subtle differences in expression. In addition, the single-stranded RNA probe for Epo mRNA is more sensitive than the nick-translated glyceraldehyde-3-phosphate dehydrogenase cDNA probe; thus, small amounts of degraded mRNA are more easily detected.

DISCUSSION

The early studies by Jacobson and co-workers¹ in nephrectomized animals clearly established the kidney as the primary source of Epo in adults. Although the ability of the kidney to produce Epo directly had been questioned,¹⁸ probes derived from the recently cloned human and mouse Epo genes have provided evidence for the direct participation of the kidney in the biogenesis of Epo.^{3,4} Our experiments demonstrate that renal Epo mRNA begins to accumulate within 1 hour of exposure to hypoxia and this accumulation parallels the rise in kidney and plasma Epo content. Discontinuation of hypoxia results in rapid decline in the level of Epo mRNA, followed by a decrease in kidney and plasma Epo. Renal Epo synthesis thus appears to be regulated by the level of its specific mRNA and these levels appear to be highly sensitive to variation in tissue oxygenation. Although

variations in mRNA probably reflect changes at the transcriptional level, possible regulatory effects influencing mRNA stability cannot be ruled out. In addition, our results suggest that renal Epo production in response to hypoxia represents *de novo* synthesis with rapid release and no significant intracellular Epo accumulation.

The localization of Epo production within the kidney has been a source of contention. Immunofluorescence studies have localized Epo to the glomeruli of hypoxic kidneys and suggested a glomerular origin of renal Epo.⁵ Furthermore, Epo has been reported to exist in extracts from isolated glomeruli of rats exposed to hypobaric hypoxia¹⁹ and that Epo-like activity can be demonstrated in conditioned medium from *in vitro* cultures of glomerular-mesangial cells.⁷ On the other hand, a tubular origin of renal Epo was suggested by Caro and Erslev,⁸ who demonstrated that the major portion of intracellular Epo in the kidney is contained in tubular cell extracts. In addition, these authors demonstrated Epo production by a proximal tubular cell line.⁹ Our studies have localized Epo mRNA to the tubular cell fraction of sieve-separated kidney tissues with no detectable Epo mRNA in the glomerular fraction. The renal tubular fraction is histologically complex, with tubular segments, interstitium and vascular elements. A precise localization of Epo mRNA within this fraction will require *in situ* hybridization experiments.

ACKNOWLEDGMENT

We thank Dr C. Shoemaker (Genetics Institute, Boston) for providing us with the mouse Epo gene and Dr R. Weinmann (Wistar Institute, Philadelphia) and Dr Hideko Kaji for their advice and support. We also thank D. Likens for his photographic work and G. Moore and D. Riso for secretarial assistance.

CONCISE REPORT

The Effect of the Plasticizer Di(2-ethylhexyl)phthalate on Red Cell Deformability

By R.S. Labow, R.T. Card, and G. Rock

Red cell concentrates (RCC) are stored for 35 to 42 days in plastic containers manufactured with the liquid plasticizer di(2-ethylhexyl)phthalate (DEHP). DEHP leaches from the polyvinylchloride (PVC) plastic bag, then binds to and stabilizes the RC membrane. This study was undertaken to determine the deformability of the RC membrane using an osmotic gradient ektacytometer and to relate these measurements to the concentration of DEHP in the stored RCC. Pooled RCC was aliquoted into PL146 (PVC), PL732 (polyolefin), and PL732 (with added DEHP) bags with samples removed weekly for analysis of osmotic fragility, deformability, and DEHP concentration. The adenosine triphosphate (ATP) content was also measured. The increase in osmotic fragility during storage was greater when RCC

was stored without DEHP. In addition, there was a decrease in the maximum elongation index (EI max) when there was decreased DEHP in the storage bag. The osmolality (Omax) at which EI max occurred, as well as the Omin, the osmolality at which minimum elongation (EI min) occurred was higher in the PL732 container than in the PL146 or in the PL732 to which DEHP had been added. These changes could be reversed by addition of DEHP at the beginning of the storage period, showing a direct correlation between DEHP concentration during storage and RC membrane flexibility. By a better understanding of the mechanism of DEHP protection, it might be possible to substitute a less toxic stabilizing compound.

© 1987 by Grune & Stratton, Inc.

IT IS WIDELY ACCEPTED that impaired red cell (RC) deformability can cause a reduction in cell survival.^{1,2} During storage in the liquid state, RCs progressively lose their viability³; this loss is associated with loss of membrane lipid⁴ and with reduced deformability.⁵ Deformability of RC membranes can be measured using osmotic gradient ektacytometry. Characteristic profiles are obtained and can be used to detect changes in membrane surface area and water content. Clark et al⁶ have shown that by selectively altering the membrane area and water content of normal cells three features of the osmotic deformability profile can be used to characterize cell populations: (1) The osmolality at which hypotonic minimum deformability or elongation (EI min) occurs, designated Omin, provides a measure of the average ratio of surface area to volume of the cell population. This value coincides with that of the osmolality at which 50% of the cells hemolyze in an osmotic fragility test. (2) For homogeneous cell populations with normal or reduced lipid content, the height of the maximum deformability or elongation index (EI max) reflects the amount of membrane surface area available for cell deformation. The position of the EI max moves to lower or higher osmolality (Omax) as the water content of the cell is decreased or increased, whereas a reduction in membrane surface area causes a reduction in maximum attainable EI. (3) A measure of initial water content of the cell can be derived from the hypertonic area of the profile by determining the osmolality at which EI reaches a particular value, since cell deformation is also determined by intracellular viscosity.

Polyvinylchloride (PVC) plastic is the most commonly used material in medical devices and was the first plastic to be used for the storage of whole blood.⁷ The plasticizer di(2-ethylhexyl)phthalate (DEHP) that is added to PVC plastic to impart flexibility, leaches from the plastic into plasma as was first reported in 1967 by Guess et al.⁸ Since that time DEHP has been found in any situation where lipid-containing biological fluids come into contact with DEHP-containing PVC plastic.⁹

Chronic toxic effects such as carcinogenicity,¹⁰ embryotoxicity,¹¹ and testicular atrophy¹² have been attributed to

DEHP and its major metabolite mono(2-ethylhexyl)phthalate (MEHP) in rodents. In order to provide blood component therapy free of these plasticizer contaminants, it would be valuable to search for non-DEHP plastic material that could be used for component storage. Recently, non-DEHP plastic bags have been introduced for platelet storage because of their enhanced gas permeability. The most commonly used materials are polyolefin (PO) plastic (with no plasticizer in the formulation) or PVC plastic with tri(2-ethylhexyl)trimellitate (TOTM) instead of DEHP as the plasticizer. Although the non-DEHP bags have increased the storage time of platelets from three to five days¹³ due to the better gas exchange, it was found that RCs are only stable for 21 days when stored in non-DEHP plastic.¹⁴ We¹⁵ and others^{16,17} have found that the DEHP that leaches out of the PVC bags binds to the RC membrane and stabilizes it. After day 14 the osmotic fragility and plasma-free hemoglobin increases much more rapidly when the RCs are stored in non-DEHP plastic^{14,17} than if stored in PVC-DEHP bags. Osmotic fragility and plasma-free hemoglobin have been correlated

directly with DEHP concentration during storage.^{15,16} In order to try to elucidate the mechanism of the DEHP protection, we measured the RC deformability using the osmotic gradient ektacytometer and correlated this to the DEHP concentration during storage and have related the characteristic measurements (Omin, EI max, Omax) to the osmotic fragility and adenosine triphosphate (ATP) content measured on the same samples.

MATERIALS AND METHODS

Preparation of RC concentrate. Whole blood was collected from O-positive donors who met all the criteria of the Canadian Red Cross Blood Transfusion Service. RC concentrate (RCC) was prepared using standard blood bank procedures. RCC (from two donors) was pooled and aliquoted by weight into three containers; the PL146 bag (PVC standard RCC storage container that is routinely used), the PL732 (polyolefin container normally used for platelet concentrate storage) to which dimethylsulfoxide (DMSO) was added, and the PL732 container with added DEHP dissolved in the same amount of DMSO. There was also a PL732 container used with no additions, and a PL146 container with DMSO added as additional controls. The DEHP was dissolved in DMSO to give a final concentration of 150 $\mu\text{g/mL}$ RCC. A stock solution of DEHP in DMSO (100 mg/mL) was prepared. DEHP 30 to 40 mg was added to give a final concentration in each unit of RCC of 150 $\mu\text{g/mL}$. The amount added was adjusted to the exact volume of RCC in the container. These three containers were stored under standard conditions. On days 0, 7, 14, 21, 28, and 35 a sample was removed from each container using sterile technique and analyzed for osmotic fragility using the method of Roy and Neteboom.¹⁸ The DEHP concentration was measured by high performance liquid chromatography (HPLC) using a modification of a previously published method.^{19,20} This study was performed in triplicate, ie, three pools of two donors for each pool were aliquoted into nine containers using the three conditions described. Since the determination for each data point was done in duplicate, the number of observations was six. This includes the ektacytometry measurements as well. All plastic containers were obtained from Fenwal Corporation, Deerfield, IL. The ATP concentrations were measured on each sampling day, according to the procedure of Beutler.²¹

Measurement of RC deformability. Part of the sample removed on days 0, 7, 14, 21, 28, and 35 (1.0 mL) was placed in a small plastic tube, packed in ice, and shipped by air at 4°C to Saskatoon, where the deformability measurements were performed the same day using a Technicon ektacytometer (Technicon Instruments Corporation, Tarrytown, NY) in the osmoscan mode. In addition, RCC was prepared and stored under standard conditions at the Saskatoon Center and the results of RC deformability compared with the RC samples that were shipped by air from Ottawa. The method consists of subjecting RC in 3.1% polyvinylpyrrolidone (PVP) to a constant fluid shear stress over an osmolality gradient from 60 to 600 mosm/kg prepared using phosphate-buffered saline. The resulting deformation was then measured and recorded continuously. The EI is a measure of RC deformability and varies with the osmolality of the suspending medium. The characteristic osmotic profile is defined by a number of indices: EI max is the maximum elongation that occurs in iso-osmolar medium (Omax); EI min is the lowest deformability that occurs in hypotonic medium (Omin).

RESULTS

The DEHP concentrations in each of the storage containers changed as was expected. The variation in the DEHP concentration (Table 1) is due to variation in the amount by

Table 1. DEHP Concentration ($\mu\text{g/mL}$ RCC)

Day	PVC	PO Plus DMSO	PO Plus DEHP in DMSO
0	22 $\pm$ 1.1	2.7 $\pm$ 1.4	155 $\pm$ 57
7	54 $\pm$ 19	4.2 $\pm$ 1.4	95 $\pm$ 10
14	89 $\pm$ 34	6.0 $\pm$ 2.1	78 $\pm$ 3
21	116 $\pm$ 54	7.4 $\pm$ 3.2	85 $\pm$ 11
28	141 $\pm$ 77	8.4 $\pm$ 4.0	78 $\pm$ 17
35	174 $\pm$ 88	9.2 $\pm$ 4.5	66 $\pm$ 12

weight of the pooled RCC in the PVC storage container. In the standard PVC container normally used for RCC storage, DEHP continued to be extracted from the plastic increasing to 174 $\pm$ 88 $\mu\text{g/mL}$ by day 35. When DEHP is added to the PO container at 0 time, there is a drop in concentration with time due to the conversion of DEHP to MEHP.²² The PO container, although manufactured without DEHP, does contain small quantities of this ubiquitous plasticizer^{19,23} of which small amounts (<10 $\mu\text{g/mL}$) are extracted during the storage period. There is less variation when the weights are taken into account in adding DEHP in DMSO to the PO container. However, the difference in DEHP concentration in the PVC and PO containers is so great that it is evident that the results obtained when measuring RC deformability and osmotic fragility were directly related to the DEHP concentration measured in the RCC.

The DMSO used to dissolve the DEHP that was added to both PO containers had no effect on any of the measurements performed in this study. All of the measurements performed on the RCC stored in the PVC container, the PO container plus DMSO, and the PO container to which DEHP in DMSO was added were also performed on RCC stored in a PL146 container to which only DMSO was added, as well as

Fig 1. RC deformability measured in RCC stored in three types of bags: PL146, PL732 plus DMSO, and PL732 plus DMSO and DEHP. (A) Day 0; (B) day 35.

in a PL732 container to which nothing was added. This was another check that all observed effects were related to DEHP concentration and not to the DMSO, with the only differences observed being related to the DEHP concentration.

Figure 1 shows the RC deformability for RC storage under all three storage conditions. Using the student's *t* test, there was a statistically significant difference between PL732 plus DMSO alone compared with PL146 or PL732 plus DMSO and DEHP; this can be clearly seen when the EI max, Omax, and Omin values are plotted separately (Fig 2) with error bars. This profile was identical for all three storage conditions on day 0 (Fig 1A). The EI varied with the

osmolality of the suspending medium and EI max occurred in iso-osmolar medium (290 mosm/kg, Omax) as was expected. EI min occurred at 140 mosm/kg (Omin). Figure 1B shows the deformability profiles of the same samples on day 35 of storage. The storage container with no DEHP had a greater loss of deformability EI max (Fig 2A). Omax values (Fig 2B) were shifted to the right, that is, toward higher osmolality. Addition of DEHP to the non-DEHP bag partially corrected the defect. With DEHP present from the start of the storage period there was a reversal Omin shift to higher osmolality (Fig 2C). The Omin values correlated directly with the 50% hemolysis point on the osmotic fragility curves (Fig 3). The data points for the osmotic fragility curves represent the mean of the values obtained from three pools. The standard deviation was calculated for the concentration of sodium chloride at 50% hemolysis for each pool for each sampling day (Table 2). There was no statistically significant difference between the PVC or the PO container in the 50% hemolysis point up to day 21 of storage. After day 21, it was evident that the increased concentration of DEHP caused a decrease in the osmotic fragility. The shift to higher percent sodium chloride was equal to the Omin shift on the deformability profiles on day 35 of storage.

Fig 2. The variation of EI max (A), Omax (B), and Omin (C) with increasing storage time in three types of storage containers: PL146, Δ ; PL732 plus DMSO, $\square$; and PL732 plus DMSO and DEHP, $\bullet$.

Fig 3. The variation of osmotic fragility with increasing storage time in three types of containers: PL146, PL732 plus DMSO, and PL732 plus DMSO and DEHP. Day 0, $\circ$; day 21, $\square$; and day 35, $\triangle$.

Table 2. Sodium Chloride Concentration at 50% RC Hemolysis

Day	PVC	PC Plus DMSO	PO Plus DEHP in DMSO
0	0.455 ± 0.013	0.448 ± 0.003	0.447 ± 0.008
7	0.452 ± 0.003	0.457 ± 0.008	0.448 ± 0.008
14	0.462 ± 0.016	0.458 ± 0.006	0.460 ± 0.013
21	0.465 ± 0.108	0.487 ± 0.012	0.467 ± 0.016
28	0.462 ± 0.022	0.488 ± 0.013	0.472 ± 0.016
35	0.467 ± 0.017	0.503 ± 0.011	0.482 ± 0.022

The ATP concentration in the RCC decreased with increasing storage time to the same extent in all three types of storage conditions (Fig 4). The differences observed are not statistically significant (student's *t* test).

DISCUSSION

Over the past few years, concern has arisen about the toxic effects of DEHP and its metabolites. We¹⁵ and others^{16,17} have shown that DEHP binds to the RC membrane and lowers its osmotic fragility. When attempts were made to store RCC in non-DEHP containers beyond 21 days, increased osmotic fragility and plasma-free hemoglobin were measured¹⁵ as well as decreased in vivo survival times.¹⁴ Horowitz et al¹⁷ stored RCC in polyethylacrylate bags and showed that RC metabolism was preserved, but the RC membrane had greatly increased fragility. We have studied the changes in RC deformability during storage and have shown that DEHP altered the membrane flexibility. The presence of DEHP enhanced RC deformability and resulted in a more "flexible" cell after prolonged storage. The fact that we observed no difference in ATP levels with different concentrations of DEHP, showed that DEHP exerted its effect directly on membrane flexibility and not on RC function. Decreased deformability is directly related to loss

Fig 4. ATP concentration in RCC—variation with storage time in three types of storage containers: PL146, Δ; PL732 plus DMSO, □; PL732 plus DMSO and DEHP, ●.

of membrane surface area, which is due to the altered cholesterol to lipid ratio.⁶ The protection by DEHP may be due to the incorporation of the very hydrophobic DEHP into the area that was vacated by the lipid, alternatively the DEHP may help by bridging the asymmetric bilayers. By a better understanding of the mechanism of this DEHP protection, it might be possible to introduce some other stabilizing lipophilic compound that would not be as toxic as DEHP.

CONCISE REPORT

Marrow Transplantation for Children With Acute Lymphoblastic Leukemia in Second Remission

By Jean E. Sanders, E. Donnell Thomas, C. Dean Buckner, and Kristine Doney

Fifty-seven children between the ages of 3 and 17 years with acute lymphoblastic leukemia (ALL) in chemotherapy-induced second bone marrow remission were given cyclophosphamide, total body irradiation, and bone marrow transplants from HLA-matched donors. Sixteen died of transplant-related complications. Eighteen relapsed between 56 and 833 days after transplantation, and 16 died of

leukemia. Two survive in remission off treatment following chemotherapy. Twenty-three survive in continuous remission from 1.4 to 10.4 years after transplantation and the actuarial analysis shows disease-free survival of 40% with a plateau extending from 2.5 to 10.4 years.

© 1987 by Grune & Stratton, Inc.

TWO RECENT REPORTS concluded that chemotherapy for children with acute lymphoblastic leukemia (ALL) in second remission results in disease-free survival equal to marrow transplantation and suggest that marrow transplantation should not be recommended for these patients.^{1,2} It seemed worthwhile, therefore, to review the experience of the Seattle transplant team with marrow grafting for similar children

MATERIALS AND METHODS

Fifty-seven consecutive children <18 years of age with ALL in second marrow remission received marrow transplants from HLA identical siblings at the Fred Hutchinson Cancer Research Center between February 1973 and July 1985 and were analyzed as of January 1, 1987. Initial marrow relapse occurred while receiving chemotherapy in 52 patients and after chemotherapy had been discontinued in five patients.

Preparation for engraftment consisted of two doses of intrathecal methotrexate (MTX) (3 to 12 mg), cyclophosphamide (60 mg/kg for two doses), and total body irradiation (TBI). Nine patients received 9.2 Gy, 34 received 10.0 Gy in a single exposure, and 14 received 12.0 to 15.75 administered as 2.0 Gy/d or 2.25 Gy/d for six or seven consecutive days. Marrow was infused immediately following the last dose of TBI. Prophylaxis for graft-v-host disease (GVHD) consisted of MTX in 55 patients and cyclosporine in two.^{3,4} The grading and treatment of acute and chronic GVHD have been described elsewhere.^{3,5} Protocols and consent forms were approved by the Institutional Review Board of the Fred Hutchinson Cancer Research Center, and all patients gave informed consent.

RESULTS

All 57 patients engrafted as shown by rising peripheral blood counts and by marrow studies, which was confirmed in 29 patients by blood genetic markers.

Fourteen patients, five with and nine without acute GVHD, died in the first 102 days, one of infection, seven of cytomegalovirus pneumonia, one of *Pneumocystis carinii* pneumonia, one of idiopathic pneumonia, two of leukoencephalopathy,⁶ one of GVHD, and one of immunoblastic sarcoma. One patient died 409 days after transplant with complications of chronic GVHD, and one patient died 470 days after transplant of leukoencephalopathy.

Eleven patients developed grade II to IV acute GVHD. Chronic GVHD occurred in eleven patients, ten with de novo onset and one after grade II acute GVHD. Seven of these 11 responded completely to immunosuppressive therapy and have Karnofsky scores of 100% off treatment and four developed recurrent leukemia.

Eighteen patients relapsed after transplantation (Fig 1). Sixteen patients died of leukemia. Two of the relapsed patients achieved a remission with chemotherapy, were treated over a 2- to 3-year period, and are in remission 6 months after discontinuing chemotherapy. Relationship of prognostic factors to relapse is shown in Table 1.

Figure 1 shows the probability of disease-free survival with a plateau at 40% extending from 2.5 to 10.4 years.⁷ Duration of first remission, WBC at diagnosis, history of extramedullary relapse, or GVHD did not influence probability of disease-free survival (Table 1).

Fig 1. Kaplan-Meier product limit estimates for probability of disease-free survival and of relapse. The open circles indicate living patients.

DISCUSSION

Recent reports suggest no difference in survival between marrow transplantation from matched sibling donors and chemotherapy for children with ALL who achieve a second remission. Chessells et al¹ reported 53 children in second remission including 40 treated with chemotherapy and 13 with a donor who were eligible for a marrow transplant. However, only ten patients were actually transplanted but all 13 were included in the transplant group analysis. After 1 to 5.5 years of follow-up the actuarial analysis showed a 5-year disease-free survival of 35% for the transplanted patients and 20% for the chemotherapy recipients, a difference that was not statistically significant. Buchanan et al² reporting for the Pediatric Oncology Group described 198 patients who achieved a second remission and were treated with further chemotherapy. Twenty-four percent survived 18+ months. Twenty-eight similar patients given an allogeneic marrow graft showed a 24% survival at 18+ months. The short follow-up and the high incidence (50%) of toxic deaths in the marrow transplantation group make interpretation of these results difficult. Rivera et al,⁸ also reporting for the Pediatric Oncology Group, described the results of intensive chemotherapy for children with ALL who relapse. Five of 31 patients (16%) who achieved a remission were alive without disease after 38 to 44 months. All five had an initial marrow remission of more than 18 months.

The Kaplan-Meier probability of disease-free survival for the 57 children in this report shows a plateau at 40% extending from 2.5 to 10.4 years. Since more than half of the survivors are now more than four years posttransplant, it is reasonable to expect that the majority are cured of their

disease. Although our patients were not part of a prospective study, the spectrum of risk factors shows that they were not selected as good risk patients.

Three single institution prospective studies of children in second remission of ALL compared the results of marrow transplantation with chemotherapy. Of the 14 children reported by Johnson et al,^{9,10} four are disease-free 7 to 10 years after transplantation while in second remission. All 21 patients treated with chemotherapy after achieving second remission relapsed and died by 3 years. The University of Minnesota actuarial relapse-free survival for 15 children treated with a marrow transplant was 33% at 36 months compared with 5% for 23 patients treated with chemotherapy.¹¹ The Genova group reported an actuarial probability of being in continuous remission at 2 years of 58% for 17 children who received marrow transplantation compared with 18% for 19 children receiving chemotherapy.¹² A review by Butturini et al suggested that marrow transplantation was superior to chemotherapy for those children who relapsed within 18 months of first remission.¹³

The therapy of childhood ALL is improving both with chemotherapy and with marrow transplantation, but we wish to emphasize the importance of long-term follow-up before meaningful comparisons can be made. Prospective studies that evaluate outcome for all children who achieve second remission are needed to determine the optimum treatment for these children, since matched sibling donors are available for only one-third of the potential recipients. Based on the present long-term data, we conclude that all children with a suitable donor who achieve a second remission should be offered a transplant.

CONCISE REPORT

Identification of a Restriction Fragment Length Polymorphism Involving the Oncogene ETS-1 on Chromosome 11q23

By Paul D. Savage, Curtis A. Hanson, and John H. Kersey

Twenty four samples of DNA from 23 unrelated individuals were analyzed for the presence of a novel restriction fragment length polymorphism (RFLP) involving the proto-oncogene ETS-1 at an *Xba* I site. Four samples from unrelated individuals lacked an *Xba* I site, giving rise to a longer restriction fragment detectable by Southern analysis; two samples were from normal tissue, and two were from acute myelogenous leukemic blasts. Thus, no association could be found between the RFLP and disease among

the individuals studied. Pedigree analysis of another cohort demonstrated Mendelian inheritance consistent with a somatic polymorphism. The practical applications of RFLP analysis in clinical and research settings, and the usefulness of this *Xba* I RFLP in the study of hematologic malignancies because of its location in 11q23, are discussed.

© 1987 by Grune & Stratton, Inc.

VARIATION IN PHENOTYPIC characteristics between individual members of a species is often the result of minor base sequence differences between the genes responsible for that phenotype. Those differences that occur at particular restriction endonuclease sites are detected following restriction endonuclease digestion and Southern analysis by the presence of fragments of varying lengths. These fragment length differences are referred to as restriction fragment length polymorphisms (RFLPs), and their analysis has been shown to be useful for a number of studies, including assistance in the mapping of genes to certain regions of the genome,¹ serving as markers for certain diseases or phenotypes,² and determination of engraftment in allogeneic bone marrow transplantation.³

Many types of malignancies, both hematologic and nonhematologic, are associated with cytogenetic abnormalities of chromosome 11 band q23 (11q23).⁴ A number of genes have been mapped to this area, including the proto-oncogene ETS-1.⁵ ETS-1 has been of interest because proto-oncogene activation, which occurs as a result of translocations, deletions, or amplification, can be important in the pathogenesis of these malignancies.

Using the genomic ETS-1 probe described by de Taisne et al.,⁵ we have looked at many cases of acute lymphocytic leukemia (ALL), acute nonlymphocytic leukemia (ANLL), and a leukemic cell line with a known translocation of 11q23.⁶ While we have not found any evidence of ETS-1 abnormalities to date, we have identified an RFLP involving ETS-1 that we wish to report here. This RFLP could be important in future studies of ETS-1 and gene mapping of the 11q23 region.

MATERIALS AND METHODS

Leukemic tissues used in this study included excess peripheral blood and/or bone marrow obtained during diagnostic work-up or relapse studies; materials were either fresh or quick frozen in DMSO and stored in liquid nitrogen. Leukemias were analyzed by routine histopathologic studies and cell marker analysis and classified according to the French-American-British (FAB) system. Cell lines were representative of human lymphoid and myeloid lineages and were used because they represented leukemias that are cytogenetically normal at 11q23; the cell line RS(4;11) was also used because it contains a known t(4;11)(q21;q23) that was described elsewhere.⁶ Normal DNA was obtained either from placentas or excess bone marrow (obtained during harvesting for bone marrow transplantation); the cell line HF-26 was also used as a source of normal DNA.

The use of all human material was approved by the University of Minnesota Committee on the Use of Human Subjects in Research; the methods and facilities used followed NIH guidelines for recombinant DNA studies.

Genomic DNA was extracted from tissue using the nuclei isolation technique as described by Bahkshi et al.⁷ Ten micrograms were then digested with the indicated enzyme under conditions as outlined by the enzyme manufacturer for four hours (Bethesda Research Laboratories, Gaithersburg, MD). The restriction fragments were size fractionated on a 0.8% agarose gel, then transferred to an activated nylon membrane (Zetabind; AMF Cuno, Meriden, CT) with 20X SSC (standard saline citrate) using the Southern technique.⁸

The probe used in this study is the 5.4 kb *Eco* RI human genomic ETS-1 probe described by de Taisne et al.⁵ Radiolabeled probes were synthesized to high specific activity using the random hexamer primer method⁹ and ³²P-dCTP.

Hybridization was performed for 48 hours in the presence of 50% formamide at 42°C. Posthybridization was performed at high stringency, the final washes being done with 0.1X SSC, 0.1% SDS at 60°C, for one hour. The blots were air dried for six hours, and exposed to Kodak XAR-5 film (Rochester, NY) at -70°C for one-half to three days.

RESULTS

In the course of experiments to evaluate possible ETS-1 rearrangements in leukemias, we found a nongermline restriction fragment on an *Xba* I digest of cells from a patient with ANLL with FAB-M4 morphology. Since multiple other enzyme digests revealed germline configuration, we sought to determine whether this was an RFLP or a pathophysiologic point mutation. In order to evaluate this question, DNA

was studied from a number of normal individuals. A Southern blot of an *Xba* I digest of total genomic DNA from 19 unrelated individuals studied with the ETS-1 genomic probe is shown in Fig 1. This probe hybridizes to restriction fragments of 6.6 kb and 1.15 kb in length in most individuals; however, four samples demonstrated a 2.4 kb restriction fragment in addition to the other two. The presence of only one additional band (2.4 kb) in the four individuals, combined with a probe size of 5.4 kb, can best be explained by loss of the *Xba* I site flanking the 1.15 kb fragment, with extension of this fragment to the next *Xba* I site, 1.25 kb away. Thus, the 2.4 kb fragment and the 1.15 kb fragment appear to be alleles. In no case did we find a homozygote who lacked the 1.15 kb fragment. This appears to represent an RFLP, in that germline configuration is found on digestion of these DNAs with other enzymes (at least three [*Bam* HI, *Eco* RI, *Hind* III], and up to eight in some cases [including *Bgl* II, *Kpn* I, *Pst* I, *Sal* I, and *Sst* I]). Further evidence that this is an RFLP resulted from demonstration that it is transmitted in a Mendelian co-dominant inheritance pattern on analysis of family members (data not shown); here, too, no homozygote for the 2.4 kb allele was found. Thus, the two alleles may be represented as follows:

Allele no.	Size (kb)	Frequency
1	1.15	0.913
2	2.4	0.087

DISCUSSION

RFLPs are useful as unique markers for certain regions of the genome; as such, they are useful to both laboratory and clinical investigators for a variety of studies. We have described a new RFLP that involves an *Xba* I site within the ETS-1 locus; it is interesting to note that the size of this other restriction fragment is approximately the same as that of the rearranged *Xba* I fragment reported by Rovigatti et al.¹⁰ This site is important as 11q23 is involved more than any other region of the genome in ANLL⁴; abnormalities of 11q23 are also reported for ALL, non-Hodgkin's lymphoma (NHL) (both 1° and 2°), solid tumors,⁴ congenital disorders,¹¹ and most recently, as the most common site of involvement when progressive cytogenetic abnormalities are seen in childhood acute leukemia.¹²

The role of the proto-oncogene ETS-1 in the pathogenesis of many of the above malignancies is unclear, although there is evidence that the ETS-1 proto-oncogene moves to chromosome 4 in at least some translocations associated with these leukemias.¹³ We have not to date demonstrated rearrangement in the cases that we have studied. The significance of this RFLP that we report here is not clear. Proto-oncogene activation may occur following point mutation, as has been demonstrated with two other proto-oncogenes,^{14,15} and it is interesting to note that we did not detect a homozygote for allele no. 2, although this latter point is most likely secondary to the small sample size. The significance of an ETS-1 point mutation can only be definitively answered once the normal ETS-1 cDNA sequence, as well as the sequences of the

Fig 1. Southern blot of 10 µg genomic DNA digested with *Xba* I, and probed with the 5.4 kb *Eco* RI genomic ETS-1 probe. Numbers at the top are lane numbers; numbers on left are restriction fragment sizes, in kilobases (kb). Lanes 1 through 4, normal controls; lanes 5 through 7, leukemic cell lines; lane 8, "normal" cell line HF-26; lanes 9 through 19, patients with acute myelogenous leukemia (AML). The RFLP is demonstrated in lanes 4, 8, and 15. The variation in band intensity from lane to lane is secondary to unequal loading of DNA.

RFLPs in both normal and pathologic tissues, has been determined. Care must be taken in analyzing this region of DNA with *Xba* I, or any restriction endonuclease whose site may partially overlap the *Xba* I site, until the exact base changes are known, since the variant length restriction fragments can be mistaken as evidence for gene rearrangement if further analysis with other enzymes is not performed.

This RFLP may be useful as a marker for a predilection to a disease or group of diseases. Our data do not support nor refute this at present, although the numbers of normal specimens and malignant subtypes are small; further studies involving larger numbers of cases are needed in order to address this issue.

We feel it is of interest to note that this *Xba* I RFLP is the fourth RFLP that has been identified within the ETS-1 locus; the other three are *Ava* II¹⁶ and two for *Sst* I.^{16,17} All four are detectable with the same probe, and three RFLPs (*Ava* II, *Sst* I, *Xba* I) lie within a few kilobases of each other.¹⁶ To date no other RFLPs have been reported within 11q23 that are not detected by ETS-1 probes.¹⁶

ACKNOWLEDGMENT

The authors wish to thank Jacques Ghysdael for supplying the ETS-1 probe used in this study, and for his helpful recommendations. We also wish to thank Cindy Vipond and Ann Kralewski for their secretarial assistance.

Localization of the G-CSF Gene on Chromosome 17 Proximal to the Breakpoint in the t(15;17) in Acute Promyelocytic Leukemia

By Ruth N. Simmers, Lorna M. Webber, M. Frances Shannon, O. Margaret Garson, Gordon Wong, Mathew A. Vadas, and Grant R. Sutherland

The human granulocyte-colony stimulating factor gene (G-CSF) is localized at 17q11.2-q21, the region of one of the breakpoints in the 15;17 chromosome translocation specific for acute promyelocytic leukemia (APL). As G-CSF induces differentiation and loss of tumorigenicity in myeloid leukemic cells or cell lines, it was possible that the translocation in APL involved the DNA of the G-CSF coding region or its regulatory region. In situ hybridization to chromosomes with the t(15;17) from patients with the APL

translocation using a G-CSF cDNA clone revealed that the coding region of this gene is proximal to the t(15;17) breakpoint on chromosome 17. Southern analysis of DNA from patients with the APL translocation showed no differences in hybridization between normal and leukemic cells. These results indicate that the G-CSF coding sequence is not disrupted by the chromosomal rearrangement characteristic of APL.

© 1987 by Grune & Stratton, Inc.

THE SPECIFIC CHROMOSOME rearrangement observed in the malignant cells of patients with acute promyelocytic leukemia (APL) involves chromosomes 15 and 17, but breakpoints in the translocation remain controversial, with that on chromosome 17 being localized variously from 17q11.2 to 17q22.¹⁻⁴ The gene that encodes for human granulocyte-colony stimulating factor (G-CSF) has been mapped to the region 17q11.2-21 by in situ hybridization.⁵ G-CSF normally stimulates progenitor cells to proliferate and differentiate into neutrophils,^{6,7} and will also stimulate leukemic cells or cell lines to differentiate into mature neutrophils.⁸⁻¹¹ It is therefore possible that the 15;17 translocation in APL involves either the G-CSF gene or its regulatory region.

As the specific chromosome rearrangement in APL divides 17q into two regions, it is of interest to know to which of these regions G-CSF maps and whether the translocation alters the in situ hybridization patterns. We have studied the t(15;17) in two patients with APL using in situ hybridization with the G-CSF probe and in four patients using Southern analysis.

MATERIALS AND METHODS

DNA studies. Bone marrow cells from patients with APL were cultured for 24 hours before being synchronized with 0.1 μ mol/L fluorodeoxyuridine.¹² The block was released by the addition of 20 μ mol/L bromodeoxyuridine and the chromosomes harvested 8½

hours later after 30 minutes' exposure to colcemid. These chromosomes were banded and photographed prior to in situ hybridization.

This was carried out using a cDNA clone consisting of the entire coding region of the G-CSF gene in the plasmid pXMT2, to these bone marrow and to normal male lymphocyte chromosomes as described by Simmers et al.⁵ Kodak NTB-2 (Rochester, NY) and Ilford L4 (Essex, UK) nuclear research emulsions were used for autoradiography.

Southern analysis was performed, using the G-CSF probe, to DNA from normal and leukemic cells of four patients with APL and the t(15;17). (DNA was kindly supplied by Professor A. Morley and Dr L. Ashman.) The DNA was cut by four restriction enzymes: *Eco* RI, *Bam* HI, *Bgl* II, and *Hind* III.

Patients. Two patients with APL were studied using in situ hybridization. Patient ML was a 72-year-old woman who presented with APL (M3) in June 1986. She died from uncontrollable bleeding shortly after admission. The leukemic cell karyotype showed the typical 46,XX,t(15;17)(q22;q21) in 95% of metaphases examined.

Patient SD was a 15-year-old boy who presented with APL in November 1984. The leukemic karyotype was 46,XY,t(15;17)(q22;q21),i(17q-); an isochromosome of the partially deleted 17q is a recognized variant of the t(15;17) in APL.¹³ The patient achieved remission, but subsequently relapsed on several occasions and although additional chromosome abnormalities were found at relapse, the t(15;17),i(17q-) was always present, with approximately 20% of metaphases having an additional i(17q-). The patient died 21 months after diagnosis.

RESULTS

Examination of 25 normal metaphases probed for G-CSF revealed significant label on the long arm of chromosome 17: 22 out of 108 silver grains (20%) were seen over this region ($P < 10^{-5}$ using cumulative Poisson probabilities), indicating that the probe had hybridized to G-CSF on 17q. Chromosomes from 121 metaphases of patient ML had 16 silver grains (6.4% of a total of 249 silver grains over all chromosomes; $P < 10^{-5}$) over the region 17cen to 17qter on the normal chromosome 17; 22 (8.8% of 249; $P < 10^{-5}$) over 17cen to 15qter on the derived chromosome 17; and four (1.6% of 249; NS) over both 15q15 to 15qter and 15q15 to 17qter on the normal and derived chromosomes 15, respectively. Chromosomes from 130 metaphases of patient SD had 14 silver grains (4.9% of a total of 287 silver grains over all chromosomes; $P < 10^{-5}$) over 17cen to 17qter on the normal chromosome 17; 44 (15.3% of 287; $P < 10^{-5}$) over the isolated 17q; and four (1.4% of 287; NS) and five (1.7% of 287; NS) over 15q15 to 15qter and 15q15 to 17qter on the normal and derived chromosomes 15, respectively. In sum-

Fig 1. The distribution of silver grains scored over the normal and derived chromosomes 15 and 17 of (A) patient ML; and (B) patient SD. Note in (B) that there are two copies of 17q⁻ in the i(17q⁻), but as it is not possible to differentiate morphologically between the two arms of the isochromosome, the label is represented on only one arm; also note that about 20% of metaphases had an extra copy of this chromosome. The regions involved in translocation are indicated by arrows.

mary, metaphases from both patients showed significant labeling of the derived and normal chromosomes 17, but not of the derived chromosomes 15 (Fig 1). These results indicate that the G-CSF coding region is proximal to the breakpoint on chromosome 17 and therefore has not been moved in the translocation.

Southern analysis failed to reveal rearrangement of the coding region of the G-CSF gene.

DISCUSSION

The chromosome 17 breakpoint of the translocation in APL cells has been located variously from 17q11.2 to 17q22.¹⁻⁴ This region overlaps with the localization of G-CSF at 17q11.2-21 recently described by Simmers et al.⁵ Thus, while the location of the G-CSF gene has not been defined more precisely by the present results, the position of the coding region with respect to the breakpoint and its probable noninvolvement in the translocation have been revealed.

The oncogene *c-erbA* has also been mapped proximal to the chromosome 17 breakpoint in APL¹⁴⁻¹⁶ and no rearrangement of the *c-erbA* gene resulting from this translocation has been detected.¹⁷ In a case of undifferentiated acute leukemia found to have a t(17;21)(q21-q22;q22), the *c-erbA* gene was localized proximal to this breakpoint at 17q21-22.¹⁴ In addition, the nerve growth factor receptor gene (*NGFR*) has been mapped distal to this breakpoint at 17q12-22.¹⁸ Although cytogenetically similar, the point of translocation in this undifferentiated leukemia is not necessarily the same at the DNA level as in the t(15;17) in APL, so it cannot be assumed that *NGFR* is actually distal to the breakpoint in APL. No rearrangement of the *NGFR* gene was detected in chromosomes with the t(17;21) or the APL translocation.¹⁸

As the G-CSF probe used for in situ hybridization in our studies contains the entire coding region of the G-CSF gene, the results indicate that these coding regions are proximal to the site of rearrangement in APL. However, this information does not exclude the possibility of the rearrangement occurring through a region of DNA flanking the coding sequence, affecting the regulation of G-CSF production.

ACKNOWLEDGMENT

We thank Dr Steven Clark for preparation of the probe.

Human Recombinant Multilineage Colony Stimulating Factor (Interleukin-3): Stimulator of Acute Myelocytic Leukemia Progenitor Cells In Vitro

By Ruud Delwel, Lambert Dorssers, Ivo Touw, Gerard Wagemaker, and Bob Löwenberg

Acute myeloid leukemia colony forming cells (AML-CFU) require the addition of colony stimulating factors (CSFs) for in vitro proliferation. Recently, we isolated a human recombinant multilineage CSF (hMulti-CSF). We investigated the ability of hMulti-CSF to stimulate AML clonogenic cells in seven patients in direct comparison with the effects of human granulocyte CSF (hG-CSF), human granulocyte-macrophage CSF (hGM-CSF), and feeder leukocytes. We show that hMulti-CSF is an efficient stimulator of AML colony formation in four of seven cases. In these patients, hGM-CSF was also capable of stimulating AML colonies in vitro. In two of seven cases hMulti-CSF appeared to be a weak stimulus of AML-CFU proliferation. In these latter two cases, however, hG-CSF and in one case hGM-CSF effectively stimulated AML-CFU growth. In one patient none of the hCSFs, either alone or in combination, induced AML colony formation, whereas AML colonies consistently appeared in the phytohemagglutinin (PHA) leukocyte

feeder assay. This finding suggests that PHA stimulated leukocytes produce components other than the tested hCSFs that may have a role in the proliferation of AML cells in vitro. Multi-CSF, like hGM-CSF, revealed a limited capacity to induce progressive maturation during AML colony growth, ie, not beyond the promyelocytic stage. On the other hand, in one case, hG-CSF stimulated the growth of AML colonies containing (meta)myelocytes and granulocytes. We conclude that hMulti-CSF is a regulator of AML-CFU proliferation in a significant number of cases. The patterns of responsiveness of AML precursors to the three hCSFs in different patients show a striking variability, which may indicate that AML-CFU are the neoplastic representatives of normal bone marrow progenitors at different stages of maturation and with distinct CSF requirements.

© 1987 by Grune & Stratton, Inc.

THE COLONY STIMULATING factors (CSFs) comprise a group of hormones that stimulate the proliferation and differentiation of hematopoietic precursor cells in vitro.¹ Recently, we isolated a human multilineage CSF (hMulti-CSF) cDNA clone from a cDNA library of phorbol ester and lectin stimulated human leukocytes.² This hMulti-CSF cDNA was identified by virtue of sequence homology occurring within the 3' terminal untranslated region of mouse interleukin-3 (mIL-3). Protein homology between hMulti-CSF and mIL-3 appeared to be low (28%).² Expression of this hMulti-CSF cDNA clone in mammalian cells resulted in the production of a CSF that stimulates the in vitro proliferation of normal hematopoietic clonogenic cells, ie, granulocytic, erythroid, and multipotent progenitors.² This hMulti-CSF is very similar to a gibbon Multi-CSF described by Yang et al³ with respect to DNA and protein sequence as well as biologic activity. In the present study we analyzed the role of this factor in the proliferation of acute myelocytic leukemia clonogenic cells (AML-CFU) in vitro. Since two other human CSFs, ie, granulocyte-macrophage CSF (hGM-CSF) and granulocyte CSF (hG-CSF), had become available earlier by recombinant DNA technology and had been demonstrated to stimulate AML colony growth in vitro,^{4,9} we examined the effect of hMulti-CSF on AML progenitors in culture in direct comparison with those hCSFs.

MATERIALS AND METHODS

AML blast cells. The blasts from seven adult patients with AML were studied. The AML cases were classified according to the criteria of the French-American-British (FAB) committee.^{10,11} AML blasts were purified from bone marrow (patients no. 1, 4, and 6) or blood (patients no. 2, 3, 5, and 7) using a bovine serum albumin (BSA) density gradient centrifugation. Contaminating T lymphocytes were removed from those cell samples by E-rosette sedimentation as described.^{12,13} All patients had given informed consent to donate bone marrow and blood.

Recombinant CSF preparations. Recombinant hGM-CSF and hG-CSF preparations were obtained from Genetics Institute (Cam-

bridge, MA). The structural and biological characteristics of these hCSFs have been reported in detail.^{4,9,14,15} Recombinant hMulti-CSF was produced in monkey (Cos1) cells by transfection of a eukaryote expression plasmid (pLB4) containing the hMulti-CSF cDNA.² Cos/pLB4 conditioned medium was harvested 48 to 72 hours after transfection. Conditioned medium from Cos cells transfected with a vector not containing the hMulti-CSF gene did not stimulate AML-CFU proliferation.

AML colony formation. AML colony numbers were assessed in the standard PHA leukocyte feeder (PHA l.f.) assay.^{12,13} Colonies (groups of 50 cells or more) were counted on days 7 through 9 of culture. To study the dependence of AML-CFU on the recombinant hCSFs, the preparations were added separately as well as in combination to the upper layer of the cultures while no feeder cells had been incorporated into the underlayers. After culture, the AML colony cells were mass harvested and analyzed morphologically on May-Grünwald Giemsa stained cytocentrifuge slides.

RESULTS

The optimal concentrations of the hCSFs to induce AML colony formation were determined in dose-response experiments (Fig 1). Based on these data further experiments were performed with 10% (vol/vol) hMulti-CSF, 0.1% (vol/vol)

Fig 1. AML colony formation (patient no. 6) with titrated concentrations of the hCSFs. (A) hMulti-CSF, (B) hG-CSF, and (C) hGM-CSF.

hG-CSF, and 100 U/mL hGM-CSF. The effects of hMulti-CSF on AML colony formation as compared with hGM-CSF, hG-CSF, and feeder leukocytes are shown in Table 1. Without the addition of any of the stimuli, no colonies were formed. AML colony formation was stimulated efficiently by hMulti-CSF in cases no. 2, 4, 5, and 6. In patients no. 2 and 6, hMulti-CSF alone induced numbers of AML colonies that exceeded the values of the standard PHA I.f. assay. In the other two cases (no. 4 and 5) suboptimal colony formation was observed, as compared with feeder leukocyte stimula-

tion. In patients no. 1 and 3, a consistent but minimal colony response to hMulti-CSF was apparent. In one case (no. 7) hMulti-CSF failed to induce AML colonies.

The stimulatory activity of hMulti-CSF on AML-CFU proliferation paralleled that of hGM-CSF, with the exception of case no. 1, in which hGM-CSF stimulated larger numbers of colonies than did hMulti-CSF. On the other hand, hMulti-CSF and hG-CSF stimulation patterns were opposite. In the cases showing a significant colony response to hMulti-CSF (cases no. 2, 4, 5, and 6) no or considerably fewer numbers of colonies were induced by hG-CSF, whereas in the hG-CSF high responders (cases no. 1 and 3) the effect of hMulti-CSF was minimal.

The data from Table 1 indicate that in most cases more than one recombinant hCSF stimulated AML colony formation. To investigate the possibility that the different hCSFs acted on AML-CFU in an additive fashion the preparations were also tested in combination. Only in cases no. 2 and 6 was an indication of additive stimulation by hMulti-CSF and hGM-CSF obtained. In the other cases the stimulatory effect of the single most efficient stimulator was not enhanced as a consequence of using a mixture of the three hCSFs in culture.

In cases no. 1, 3, 4, and 5 it appeared that AML colonies were induced more efficiently in the PHA I.f. assay than in the cultures with the complete mixture of recombinant hCSFs. Moreover, AML-CFU from patient no. 7 did not respond to the three hCSFs, whereas significant numbers of colonies appeared in the PHA I.f. assay. These data suggest that feeder leukocytes may produce at least one other component regulating AML-CFU proliferation.

The AML colony cells of patients no. 1, 3, and 6 were harvested and analyzed morphologically to assess whether the CSFs differ in their capacity to induce maturation (Table 2, Fig 2). In these cases the colony cells from the cultures stimulated by either hMulti-CSF or hGM-CSF showed limited differentiation, ie, not beyond the promyelocytic stage. In contrast, hG-CSF-stimulated colonies from patient no. 6 contained cells that had matured towards (meta)myelocytes and granulocytes (Fig 2).

DISCUSSION

We investigated the stimulative effects of hMulti-CSF, in comparison with the effects of hG-CSF and hGM-CSF and feeder leukocytes on the proliferation and differentiation of

†Percentages of 250 cells counted.

AML-CFU in colony culture. Human Multi-CSF, hG-CSF, and hGM-CSF were all capable of stimulating AML colony formation in vitro, although the responses of AML-CFU of different individuals to these hCSFs were variable.

The results indicate that AML colony formation in only one of these patients was stimulated predominantly by one of the three hCSF tested (case no. 3). Usually two (cases no. 1, 2, 4, and 5) or all three hCSFs (case no. 6) were able to induce AML-CFU proliferation. In most of these patients the presence of the three hCSFs in the cultures simultaneously did not result in an increased colony response as compared with the single most active factor, suggesting that the different hCSFs acted on overlapping AML-CFU target populations. However, exceptions were patients no. 2 and 6 in whom additive effects of hMulti-CSF and hGM-CSF on AML colony formation were observed. Thus, in these cases different AML-CFU subpopulations were apparently stimulated by different growth stimuli. The data in Table 1 do not

provide evidence that the combination of the three factors can enhance colony numbers synergistically. To explore further the possibility of a synergistic action of the hCSFs, we set up cultures to which suboptimal concentrations of the different growth stimuli were added simultaneously. These studies also did not indicate synergistic stimulation of AML colony formation by these hCSFs (data not shown).

An interesting observation was that in patient no. 7 AML colony growth could not be induced by the recombinant hCSFs, whereas colonies appeared consistently in the standard PHA l.f. assay. The PHA l.f. colony culture has been an efficient assay for clonogenic AML cells,^{12,13} although the active stimulatory components of the system are probably multiple and not exactly defined. The fact that colony growth in patient no. 7 appeared only in the PHA l.f. assay could imply that components other than these hCSFs have a critical role in stimulating the proliferation of AML precursor cells. This suggestion is also supported by the fact that in

Fig 2. May-Grünwald Giemsa morphological analysis of AML cells (patient no. 6). (A) Preculture, (B) cultured with hMulti-CSF, (C) cultured with hGM-CSF, and (D) cultured with hG-CSF.

4 cases (no. 1, 3, 4, and 5) the PHA I.f. system supported the outgrowth of larger numbers of colonies than was achieved with the mixture of recombinant hCSFs.

Morphologic analysis of the AML colony cells of three patients revealed that progressive maturation occurred occasionally in the hG-CSF stimulated but not in the hMulti-CSF and hGM-CSF stimulated cultures (Table 2). Since the three factors have been reported to induce granulocytic or monocytic differentiation in normal bone marrow cultures, this could indicate that in patient no. 6, the AML blasts respond abnormally to hMulti-CSF and hGM-CSF but normally to hG-CSF, as regards the induction of maturation.^{1,2} However, at this stage, the possibility cannot be excluded that differentiation towards granulocytic end cells, observed in the normal bone marrow cultures stimulated by hMulti-CSF or hGM-CSF, is not caused by direct effects of these two factors but by endogenously produced G-CSF.

Thus, it remains unclear whether the variations of CSF responses of AML progenitors either represent leukemic characteristics of the cells or reflect the features of normal bone marrow progenitor subsets at different maturation stages with distinct CSF requirements. To discriminate between these two possibilities it will be essential to study in detail the effects of the recombinant hCSFs on highly purified normal bone marrow progenitors.

ACKNOWLEDGMENT

The authors wish to thank Mieke Berends, Herman Burger, Marius van der Haven, Lianne Broeders, Loes van Eijk and Hans Hoogerbrugge for their technical assistance; Joke Krefft for cytological examinations; and Thea van Vlijmen, Marianne Slotboom, and Aloysia Sugiarsi for preparing the manuscript. Recombinant hGM-CSF and hG-CSF were gifts from Genetics Institute, Cambridge, MA.

CORRESPONDENCE

GAMMA INTERFERON AND APLASTIC ANEMIA

To the Editor:

Certain aspects of the published data on the role of γ -interferon (IFN- γ) in hematopoiesis in vitro and in bone marrow failure states were not emphasized in the article by Torok-Storb and co-workers.¹

Beginning with the initial observation of Kagan and colleagues,² many investigators have demonstrated that T cells from patients with aplastic anemia can suppress hematopoiesis in vitro.³⁻⁵ Bacigalupo and associates⁶ found that the supernatants of aplastic lymphocyte cultures were as effective as the cells themselves in suppression and that lectin-activated normal lymphocytes produced an inhibitory factor. These observations were important because they implicated a soluble inhibitory factor and suggested an experimental system that would avoid the allogeneic effects and imprecision that plague co-culture experiments.

We reported that the inhibitory activity in these lymphocyte supernatants was IFN- γ ;⁷ our studies have been confirmed by Murphy and colleagues,⁸ who found also that lymphotoxin was produced and acted to enhance the activity of IFN- γ , a not unexpected result given the coordinated expression of lymphokines in T cells and the known synergy between factors in inhibiting cell proliferation. Interferon production by an activated lymphocyte with the same surface phenotype as is found in the circulation of aplastic patients (CD8⁺, Tac⁺, HLA-DR⁺)⁹ has also been confirmed in other laboratories.¹⁰

In analysis of patient material, we¹¹ reported multiple abnormalities of interferon production: (a) enhanced production of interferon by lectin-stimulated mononuclear cells; (b) spontaneous production of interferon, not seen in normal cultures; (c) improvement in colony formation by aplastic bone marrow in the presence of antibodies to interferon; and (d) elevated serum levels of interferon in about 30% of patients, as determined by bioassay of fresh material by a specialist in interferon who was blinded to the clinical nature of the samples.

Abnormalities of interferon production in aplastic patients have been confirmed by other laboratories¹²⁻¹⁵ (and E.D. Zanjani, personal communication); even the abstract cited in support by Torok-Storb and co-workers concluded that "there were IFN- γ abnormalities in some patients with aplastic anemia."¹⁵ The data presented in the article by Torok-Storb and co-workers are indeed also similar to those of Zoumbos and colleagues.¹¹ First, more than one-third of patients' cells spontaneously produced interferon, in some cases to very high levels. Second, although Fig 2 (of Torok-Storb article) is plotted on a semilogarithmic scale that tends to compress the data lines, extraction of the interferon values at the plateaus and their statistical analysis shows a significant difference between lectin-stimulated interferon production by the four patients and five controls ($P < .05$ by Student's t test), again similar to the data of Zoumbos and colleagues and other investigators.

That supernatants derived from patient's cell cultures containing high concentrations of interferon did not inhibit in the study of Torok-Storb and co-workers is almost certainly due to the concomitant presence of growth factors (GM-CSF). Growth factors are antagonistic to interferon's actions in hematopoietic cell culture systems.¹⁶ More important, a major aim of our studies was to replace co-culture experiments with measurements of specific molecules and cell types. That interferon—recombinant IFN- γ —is inhibitory of hematopoietic cell proliferation has been reported by many laboratories¹⁶⁻²⁰ and in human patients treated with interferon.²¹ Torok-Storb and co-workers²² have been unable to demonstrate recombinant interferon's inhibitory effect in their cell culture system.

Finally, legitimate debate exists on the presence of interferon in serum. Our data^{7,11} were generated using the virus inhibition assay, which has recently been shown to detect lymphotoxin as well as interferon.²³ The synergy between these factors probably makes the bioassay more sensitive but less specific than the radioimmunoassay. Bioassays are not intrinsically less valuable than radioimmunoassays, however. Radioimmunoassays with monoclonal antibodies rely on detection of single or restricted numbers of epitopes, which can differ between natural and recombinant molecules²⁴ and may be lacking on molecules produced in pathologic states. In addition, molecules with very high specific activity, such as interferon, may be easier to detect with biologic than chemical techniques. Nevertheless, preliminary data obtained by Dr Leonidas Plataniotis in our laboratory (Fig 1), however, suggest that some patients with aplastic anemia will have circulating IFN- γ in their sera.

Ample laboratory data and clinical observations continue to make immune mediation of bone marrow failure an attractive hypothesis. It seems likely to me that hematopoietic depression will be effected by inhibitory molecules and that these abnormalities of the immune system reflect a viral pathogenesis, for which there is increasing evidence. The immunologic and hematopoietic systems are enormously complicated, however, and extrapolation from in vitro experiments to pathogenic mechanisms is an increasingly daunting task. Whatever interpretation eventually proves correct, it should be clear that, despite the negative title and tone, many of the differences described in the article by Torok-Storb and co-workers and in our own results, as well as those of other investigators, are more apparent than substantial.

RESPONSE

To the Editor:

In response to Dr Young's letter, I would like to reiterate three points. First, we reported that γ -interferon (INF- γ) could not be detected in serum samples obtained from 50 patients with aplastic anemia (AA). We thought this information should be published because it differed dramatically from that of Zoumbos and colleagues,¹ who detected significant levels (>10 U/mL) in 41% or 10 of 24 patients studied. Dr Young's data, published above, now indicate that 17% or 11 of 63 patients studied had serum levels >10 U/mL, which differs significantly from his previous observations.

Second, in their original publication, Zoumbos and colleagues stated that "Virtually every patient with aplastic anemia reported in this study showed abnormal interferon production in vitro." Their data indicated dramatic differences in the kinetics of INF production. Patient peripheral blood mononuclear cells (PBMCs) produced $>1,000$ U/mL of INF- γ 24 hours after lectin stimulation, and

levels continued to increase over seven days. In contrast, normal PBMC reached peak levels of $<1,000$ U/mL at day 5 and decreased to baseline levels by day 7. Our data differed dramatically from these observations. Both normal and AA PBMCs reached plateau levels of INF- γ three days post-lectin stimulation, and in both groups INF- γ levels were maintained over seven days. Clearly, in our hands the kinetics of INF- γ production did not differ between the two groups.

Third, we too believe it is noteworthy that we cannot demonstrate inhibition of BFU-E with INF- γ . This continues to be the case. Indeed, using enriched populations of precursors, we often see INF- γ augmenting BFU-E growth. Comparable results using MY 10-selected precursors have recently been reported by Strauss and associates.² These observations cannot be explained merely by the presence of GM-CSF in our cultures. Because growth of hematopoietic precursors in vitro requires growth factors, either added from exogenous sources or produced in situ, it is safe to assume that all

culture systems that support colony or burst formation contain growth factors. The explanation of these apparent and substantial differences is not obvious, but developing ways to address these issues is best served by considering both positive and negative data.

ERRATA

In the article by Viskup, Tracy, and Mann entitled "The Isolation of Human Platelet Factor V," which appeared in the April 1987 issue (Volume 69, pp 1188-1195), there were mistakes in the legend to Figure 3. The correct legend appears below:

Fig 3. Immunoblot of human platelets drawn directly into protease inhibitors and washed as described. The primary antibody was burro antihuman factor V followed by ¹²⁵I-Protein A. Lanes: (a) washed platelets (5×10^7 platelets) lysed with glacial acetic acid; (b) washed platelets (5×10^7 platelets) lysed with detergent (SDS); (c) human plasma (7.5 uL); (d) human serum (7.5 uL).

In the article by Kelleher et al entitled "Synergism Between Recombinant Growth Factors, GM-CSF and G-CSF, Acting on the Blast Cells of Acute Myeloblastic Leukemia," which appeared in the May 1987 issue (Vol 69, pp 1498-1503), there was an error in the legend for Figure 2. The correct legend appears below:

Fig 2. A photomicrograph of blast colonies formed with different growth factors. (A) GM-CSF alone at a maximum stimulatory concentration of 2 nmol/L. (B) G-CSF alone at maximum stimulatory concentration of 200 U/mL. (C) 10% HTB-9 CM. (D) A mixture of GM-CSF and G-CSF, both at maximum stimulatory concentrations.

In the article by Sugarman, Devine, and Rosse entitled "Structural and Functional Differences Between Decay-Accelerating Factor and Red Cell Acetylcholinesterase," which appeared in the September 1986 issue (Vol 68, pp 680-684), a mathematical error was consistently made in Table 1. The correct table appears below:

Table 1. The Effect of Antibodies to AChE or DAF on the Activity of AChE

Normal RBC Pretreated With	AChE Activity (moles hydrolyzed/min/cell $\times 10^{-15}$)
Anti-AChE (AE-2)	0.53
P3 control*	0.73
Rabbit anti-DAF	0.93
Normal rabbit serum	0.70

*Monoclonal antibody lacking reactivity with RBC.

ANNOUNCEMENTS

THE THIRTEENTH CONGRESS OF THE EUROPEAN SOCIETY FOR MEDICAL ONCOLOGY (ESMO)

**October 30–November 1, 1988
Lugano, Switzerland**

The program contains two key-note lectures, an award-lecture for an outstanding young investigator, and nine sessions with proffered papers and posters, followed by a review. The first day will be devoted to satellite symposia and to the educational program.

For further information, contact: F. Cavalli, MD, Division of Oncology, Ospedale San Giovanni, 6500 Bellinzona, Switzerland.

ELEVENTH ANNUAL CANCER SYMPOSIUM SEVENTH ANNUAL CANCER SYMPOSIUM FOR NURSES

October 19-21, 1987

Sheraton Harbor Island Hotel East, San Diego, CA

Sponsored by Scripps Memorial Hospital. For the Eleventh Annual Cancer Symposium, the registration fee is \$350; accreditation is 21 hours Category I. For the Seventh Annual Cancer Symposium for Nurses, the registration fee is \$275; accreditation is 23.5 contact hours.

For further information, contact: Nomi Feldman, Conference Coordinator, 3770 Tansy, San Diego, CA 92121. Telephone: (619) 453-6222.

NEW SOLUTIONS TO OLD PROBLEMS IN SURGICAL PATHOLOGY

October 5-7, 1987

Bethesda, MD

The three day program will address difficult or evolving areas of surgical pathology, and will focus on areas that often pose diagnostic difficulty. New techniques applicable to the general surgical pathology laboratory will be presented, and clinico-pathologic correlations of morphologic diagnoses will be stressed. Participants will receive a syllabus containing lecture outline material and references. The program is designed for pathologists at the senior resident and practitioner levels. Twenty-one (21) hours AMA Category I credit.

For further information or application, please call or write: Surgical Pathology, c/o FAES, National Institutes of Health, Bldg 10, Room B1-L-101, Bethesda, MD 20892. Telephone: (301) 496-7975.

AMERICAN SOCIETY OF HEMATOLOGY
TWENTY-NINTH ANNUAL MEETING

December 5-8, 1987

Sheraton Washington/Omni Shoreham Hotels
Washington, DC

The Twenty-Ninth Annual Meeting of the American Society of Hematology will be held at the Sheraton Washington and Omni Shoreham Hotels, Washington, DC, December 5-8, 1987. Programs by the Education Committee and the Scientific Subcommittees will be held on Saturday, December 5, and Sunday, December 6. The Presidential Symposium will be Tuesday morning, December 8. Four mini-plenary sessions will be held on Tuesday afternoon. Selected papers submitted to the meeting will be presented either in oral or poster sessions on Sunday, December 6, Monday, December 7, and Tuesday, December 8.

The abstract deadline for contributed papers is September 1, 1987. Abstract forms may be obtained from SLACK, Inc (address below). Subsequent issues of BLOOD will contain details of the Educational and Subcommittee Programs and the Presidential Symposium, in addition to information about registration for the meeting. Preregistration material will be sent early this fall to members. If you do not receive your meeting information by October 6, 1987, please contact the Registration Supervisor at SLACK, Inc, 6900 Grove Rd, Thorofare, NJ 08086-9447, (609) 848-1000. Nonmembers wishing to receive preregistration information and forms should also contact SLACK, Inc.

AMERICAN SOCIETY OF HEMATOLOGY
29TH ANNUAL MEETING

December 5-8, 1987

ADVANCE REGISTRATION

NAME _____ STREET _____

CITY _____ STATE _____ ZIP _____

Announcing

RETROVIR[®] (zidovudine)

The first effective treatment for certain
AIDS and other serious HIV* infections

AZT[™] (azidothymidine)
IS NOW

RETROVIR[®] (zidovudine)

*Human immunodeficiency virus

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (zidovudine)

New hope for many AIDS/ARC patients

A multicenter study proved...

RETROVIR can prolong the lives of certain AIDS and ARC patients

- In a double-blind placebo-controlled clinical trial (N = 281), only one death occurred among 144 RETROVIR patients *v* 19 deaths of the 137 patients on placebo ($p < 0.001$). The study population consisted of AIDS patients within 120 days of their first diagnosis of *Pneumocystis carinii* pneumonia or patients with more severe manifestations of AIDS-related complex (ARC)
- The probability of 24-week survival for any patient in the RETROVIR group was 0.98 compared to 0.78 for the placebo group

Comparative Mortality of RETROVIR and Placebo Group Patients in Controlled Clinical Trial (stratified by diagnosis and T4 count) n = 281

Stratum	Group Assigned	Number of Deaths	Stratum	Group Assigned	Number of Deaths
AIDS (n=160)	RETROVIR	1	Higher T4 count ($\geq 100 \leq 500$) (n=100)	RETROVIR	0
	PLACEBO	12		PLACEBO	4
ARC (n=121)	RETROVIR	0	Lower T4 count (< 100) (n=181)	RETROVIR	1
	PLACEBO	7		PLACEBO	15
Total Deaths			RETROVIR		
			1		
			PLACEBO		
			19		

RETROVIR® (zidovudine) reduced the risk and severity of opportunistic infections

- RETROVIR significantly reduced the probability of acquiring opportunistic infections in AIDS and ARC patients ($p < 0.001$)
- Severity of opportunistic infections was significantly reduced in RETROVIR patients as compared with controls ($p < 0.005$)
- In the controlled trial, no opportunistic infections occurred in ARC patients who had received at least six weeks of RETROVIR therapy. Some ARC patients developed opportunistic infections in the follow-up period while on drug

Probability of Developing Opportunistic Infection Within 24 Weeks

(Excludes opportunistic infections acquired within six weeks of entry into the study)

WARNING

WARNING: Therapy with RETROVIR® (zidovudine) is often associated with hematologic toxicity including granulocytopenia and severe anemia requiring transfusions (see WARNINGS). In addition, patients treated with zidovudine may continue to develop opportunistic infections (OIs) and other complications of the acquired immunodeficiency syndrome (AIDS) and AIDS-related complex (ARC) caused by the human immunodeficiency virus (HIV). Therefore, patients on zidovudine should be under close clinical observation by physicians experienced in the treatment of patients with diseases associated with HIV. The safety and efficacy of zidovudine have been established only for certain adult AIDS and advanced ARC patients (see INDICATIONS AND USAGE).

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (zidovudine)

New hope for many AIDS/ARC patients

RETROVIR improved immune status

- T4 cell counts in the RETROVIR group remained significantly higher than in the control group throughout the study
 - In some RETROVIR patients, particularly those with lower T4 cell counts at entry, T4 cell numbers increased, then subsequently declined
 - In contrast, placebo-group patients experienced a progressive decline from baseline in number of T4 cells
- The number of positive delayed hypersensitivity skin test conversions was significantly higher in the RETROVIR group ($p < 0.001$)

Change in T4 Cell Count

Patients' general health improved

- Patients on RETROVIR® (zidovudine) maintained their high Karnofsky performance scores (an index measuring ability to perform activities of daily life), whereas placebo group patients' scores declined
- RETROVIR patients experienced significantly fewer symptoms related to HIV infection than those on placebo
- Patients on RETROVIR therapy maintained their body weight throughout the study, whereas placebo group patients progressively lost weight

Change in Karnofsky Score for All AIDS/ARC Patients Combined

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (zidovudine)

New hope for many AIDS/ARC patients

Clinical studies showed...

It is important to identify patients at greatest risk for bone marrow toxicity, and subsequent RBC and WBC suppression, and monitor carefully

- 25% of RETROVIR patients developed anemia (<7.5 g/dl) as compared to 4% in the placebo group. This adverse reaction was most likely to occur in AIDS patients and patients with lower numbers of T4 cells
- 31% of RETROVIR patients required at least one transfusion, compared with 11% of placebo patients
- Granulocyte depression ($<750/\text{mm}^3$) was observed in 39% of RETROVIR patients as compared with 9% of placebo patients. Granulocytopenia occurred more frequently in AIDS patients and patients with lower T4 cell counts

Clinical adverse events

- Although the majority of patients in *both* the RETROVIR (84%) and control groups (72%) reported the occurrence of at least one adverse event, nausea, myalgia, insomnia, and moderate-to-severe headache were significantly more frequent among RETROVIR patients

The potential hematologic toxicity of RETROVIR plays an important role in patient management

- The majority of patients who required adjustment of RETROVIR dosage had hematologic toxicity, specifically anemia or granulocytopenia, usually occurring within the first four to eight weeks of RETROVIR therapy
- Because of this potential, careful monitoring of hematologic indices is recommended every two weeks*

Drug interactions must be considered with RETROVIR

- Concomitant use of acetaminophen with RETROVIR may potentiate granulocytopenia; other drugs that may interfere with RETROVIR metabolism or excretion (eg, probenecid, lorazepam, indomethacin, cimetidine) should be avoided

RETROVIR—the newest antiviral breakthrough from Burroughs Wellcome Co.—is the first effective treatment for certain HIV infections.

*RETROVIR dose interruption may be required for significant anemia or granulocytopenia until evidence of bone marrow recovery is observed. A reduction in daily dose may be adequate for less severe depression of RBC/WBC counts.

**Since the initial supply of RETROVIR®
(zidovudine) is limited, a special distribution
program is in place**

- Rapidity of development and complexity of the production process have limited the current supply of RETROVIR
- To help ensure a continuous supply of RETROVIR for patients at greatest need and those who would benefit most from treatment during this period of limited supply, a special distribution program has been established
- An independent group of experts from the Infectious Disease Society of America (IDSA) has assisted in developing this program for the best utilization of RETROVIR

**Patients can be enrolled in the RETROVIR
distribution program now**

- You can apply to enroll your patients in the RETROVIR distribution program at this time
- If you are currently treating AIDS or ARC patients and need additional information, call 1-800-843-9388
- Detailed information and enrollment applications are also available from your Burroughs Wellcome Co. Sales Representative
- Only patients enrolled in the distribution program will be able to receive RETROVIR

**Burroughs Wellcome Co.:
Leader in Antiviral Research**

- Continuing clinical trials to evaluate further the role of RETROVIR in the treatment of HIV infections
- Conducting research for antiviral agents effective against varicella-zoster, Epstein-Barr, human papilloma, hepatitis B virus, and cytomegalovirus
- Providing physicians with antiviral products effective against herpes simplex — today's hope for patients with genital herpes
- Pledging to keep you updated as new information becomes available

*If you have patients with
HIV infections and need
additional information,
please call*

1-800-843-9388

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OIs) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper/inducer) lymphocyte count of less than 200/mm³ in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 150 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss (≥ 15 lbs or $> 10\%$ of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 cells/mm³ at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of $< 750/\text{mm}^3$. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count $< 1000/\text{mm}^3$ or hemoglobin < 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 $\mu\text{g}/\text{ml}$ and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/TK⁺ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 $\mu\text{g}/\text{ml}$). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 $\mu\text{g}/\text{ml}$ and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 $\mu\text{g}/\text{ml}$ and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 $\mu\text{g}/\text{ml}$.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether

zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in the placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudine, 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicities was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entry, and directly related to dose and duration of therapy. The frequency of granulocytopenia and anemia according to the patients' CD4 (T4) levels is shown in the following table:

Abnormality	Pretreatment CD4 (T4) Levels			
	$\leq 200/\text{mm}^3$		$> 200/\text{mm}^3$	
	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia ($< 750/\text{mm}^3$)	47%	10%	10%	3%
Anemia (Hgb < 7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudine, examining the degree of change when compared to baseline, as shown in the table below, may be more informative.

Abnormality	% Decrease from Baseline	Pretreatment CD4 (T4) Levels			
		$\leq 200/\text{mm}^3$		$> 200/\text{mm}^3$	
		Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	$> 50\%$	55%	19%	40%	13%
Anemia	$> 25\%$	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasing macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseline symptoms and clinical abnormalities. The following table summarizes those reported clinical adverse events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nausea, insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4			
Fever	16	12	NERVOUS		
Headache	42	37	Dizziness	6	4
Malaise	8	7	Insomnia	5	1
			Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4			
GI Pain	20	19	SKIN		
Nausea	46	18	Rash	17	15
Vomiting	6	3	SPECIAL SENSES		
			Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are listed below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudine recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pain, lymphadenopathy.

Cardiovascular: vasodilation.

Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gums, rectal hemorrhage, mouth ulcer.

Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.

Nervous: anxiety, confusion, depression, emotional lability, nervousness, syncope, loss of mental acuity, vertigo.

Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.

Skin: acne, pruritus, urticaria.

Special senses: amblyopia, hearing loss, photophobia.

Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (two 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and duration of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serious anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur as early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of < 7.5 g/dl or reduction of $> 25\%$ of baseline) and/or significant granulocytopenia (granulocyte count of $< 750/\text{mm}^3$ or reduction of $> 50\%$ from baseline) may require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia or granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anemia, dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occurs following dose modification, gradual increases in dose may be appropriate depending on hematologic indices and patient tolerance.

North Carolina 27709

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to *BLOOD*. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: *BLOOD* will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the *BLOOD* Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared

in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in *BLOOD* represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a \$50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to *BLOOD* and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of *BLOOD* will assume that the authors of research papers published in *BLOOD* are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and two complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least ⅛ inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

B CELL ACTIVATION GOT YOU PUZZLED?

COULTER HAS THE SOLUTION.

Our three new B cell markers make it possible to study B cell ontogeny from pre-B stem cells to plasma cells. B5 and B6 (CD23) are found on activated B cells, and not on resting B cells. The wide expression of the B5 antigen on B cell malignancies provides evidence for the hypothesis that all B cell malignancies are derived from subpopulations of activated B cells. B3 (CD22) is clearly unique: B3 is expressed on some pre-B cells, approximately 75% of resting B cells, and is lost with activation. Expand your research on AIDS, autoimmune diseases, and lymphoproliferative disorders with this complete series of B cell monoclonals. For more information, call 1-800-327-3778 (in Florida, 1-800-432-6518, Ext. 6880). Ask us about our complete line of monoclonal antibodies and support products.

NOW THE WAY IS CLEAR FOR YOU TO PROVIDE LEUKOPOOR PLATELETS

...WITH THE CUTTER LEUKOTRAP™ PLATELET POOLING SYSTEM.

Now, leukopoor platelets can be routinely used for treatment of patients on platelet therapy to reduce or eliminate leukocyte-associated transfusion reactions. Leukotrap is the first commercially available system for routine production of leukopoor platelets.

MOST EFFICIENT METHOD
The Leukotrap System removes 90% of leukocytes and residual red cells with only 10% platelet loss.

Leukotrap™ Pooling Bag shown after completed procedure with leukocytes and residual red cells trapped in the pouch.

SIMPLE, FAST PROCEDURE

The Leukotrap System requires minimal technician time and a standard centrifuge.

Provide a better platelet product...with the Leukotrap Platelet Pooling System.

SCOTT & WHITE

HEMATOLOGISTS AND MEDICAL ONCOLOGISTS

The Scott and White Clinic and Texas A&M University College of Medicine, Temple, Texas, is recruiting two additional hematologists and two additional medical oncologists to join the current six-physician Division of Hematology/Medical Oncology. Scott and White is a 300-physician multispecialty clinic with adjacent hospital located in a city of 50,000 in Central Texas. The positions combine patient care, educational, and investigational responsibilities, and are open at the Assistant, Associate, or full Professor level depending on qualifications and prior experience. The hematologists will concentrate on classical hematologic problems and hematologic malignancies. Special interest and expertise in laboratory and clinical coagulation is sought. Oncologists' responsibilities will include planning and directing a clinical research program and developing special therapeutic techniques.

Send inquiries and curriculum vitae to:

Mr. E. Smith
Department of Internal Medicine,
Scott and White - Temple, Texas 76508
Or call 817-774-2580

DIRECTOR OF HEMATO/IMMUNOPATHOLOGY LABORATORY

The Department of Pathology at New York University Medical Center has an opening for the position of Director of the Hemato/Immunopathology Laboratory. This Laboratory has been recently renovated with excellent technical and financial support; it serves as a referral center for diagnosis of lymphoma and leukemia and plays an important role in the Cancer Center. We are searching for an individual with a complement of multimodal diagnostic skills, with an active research program of her/his own, and with interest in collaborating with immunologists and molecular biologists of the department. Faculty position and salary commensurate to the level of experience. New York University Medical Center is an Equal Opportunity Employer.

Please forward your curriculum vitae, statement of interests and the names of three referees to:

Vittorio Defendi, M.D.

Chairman, Department of Pathology
New York University Medical Center
550 First Avenue
New York, NY 10016

CANADIAN RED CROSS SOCIETY BLOOD TRANSFUSION SERVICE OTTAWA CENTRE DEPUTY MEDICAL DIRECTOR POSITION

The Ottawa Centre of the Canadian Red Cross Society, Blood Transfusion Service is inviting applications from physicians for the position of DEPUTY MEDICAL DIRECTOR.

The position involves major responsibility for a full service apheresis unit providing both cell support and plasma exchange services to a population of 800,000. The Deputy Medical Director participates in research and development programs and assists the Medical Director in general administration of the blood program. The Centre currently collects, tests, processes and issues approximately 65,000 units of blood annually. Applicants must be Canadian or American Board certified or equivalent.

Interested applicants should apply in confidence giving all details of experience and expected salary requirements to:

Dr. G. Rock
Medical Director
The Canadian Red Cross Society
Blood Transfusion Service
85 Plymouth Street
Ottawa, Ontario K1S 3E2

Be Immortal.

If you could look into the eyes of generations yet to come, you would be there. You can make a difference.

By including the American Cancer Society in your will, you can have a powerful effect on those who come after you.

And leaving a legacy of life for others is a beautiful way of living forever yourself.

 **AMERICAN CANCER SOCIETY***

This advertisement prepared by

HEMATOLOGIST— COAGULATIONIST

The Division of Hematology-Oncology at the University of Utah is seeking a coagulationist with strong laboratory research interests for a full time faculty appointment at the rank of Assistant or Associate Professor. A very competitive salary and benefits package will be adjusted according to previous experience. Please send curriculum vitae and the names of three references to: James P. Kushner, M.D., Chief, Division of Hematology-Oncology, University of Utah Medical Center, Salt Lake City, Utah 84132.

Application deadline is September 30, 1987. Applications submitted after deadline date may be considered if no suitable candidates have applied by the deadline.

The University of Utah is an Equal Opportunity-Affirmative Action employer.

UNIVERSITY OF FLORIDA—Seeks an Assistant/Associate Professor in Medicine with M.D. or M.D./Ph.D. Individual should be experienced academic hematologist with active research program to join Hematology/Oncology divisions. Position will include teaching Hematology, patient care and conducting research projects. Recruiting deadline: July 31, 1987, Starting date: September 1, 1987. Contact: Ward Noyes, M.D., University of Florida, Department of Medicine, Box J277 JHMHC, Gainesville, Florida 32610.

AN EQUAL EMPLOYMENT OPPORTUNITY/
AFFIRMATIVE ACTION EMPLOYER.

PEDIATRIC HEMATOLOGIST/ ONCOLOGIST

The Department of Pediatrics at Dalhousie University is seeking a third hematologist/oncologist whose duties would be 50% clinical/teaching and 50% research and who would have a joint university-hospital appointment. Experience in cell proliferation, retroviruses or oncogenes a definite asset.

Dalhousie University is an equal opportunity/affirmative action employer.

Please send resume and the names of three references to:

POSTDOCTORAL FELLOWS IN TRANSFUSION MEDICINE

The Blood Center of Southeastern Wisconsin offers a training program for physicians interested in a career in blood transfusion medicine. Trainees receive instruction in immunohematology, immunogenetics, transplantation, immunology, and hemostasis. Clinical rotations on a hematology/oncology and coagulation services can be arranged. The trainees participate in teaching activities and gain experience in the administrative aspects of blood banking. Opportunities for basic and applied research in transfusion therapy, platelet immunology and physiology and hemostasis are available. Board certification or eligibility in hematology/oncology or clinical pathology is required. Positions are available starting July 1, 1988. Send CV to Jay Menitove, M.D., Medical Director, The Blood Center of Southeastern Wisconsin, Inc., 1701 West Wisconsin Avenue, Milwaukee, WI 53233.

BOARD REVIEW COURSE IN MEDICAL ONCOLOGY

**The George Washington University
Medical Center
Washington, DC**

October 14-18, 1987

The Division of Hematology and Oncology of the George Washington University Medical Center is pleased to announce this course to be held at the Omni Shoreham Hotel, October 14-18, 1987, in downtown Washington, DC.

Designed to meet the needs of physicians planning to take the medical oncology boards, this course will be a valuable update on the recent advances in oncology. It will satisfy the requirements for up to 37 hours of category I AMA credit. The course director is Philip Cohen, M.D.

For further information and registration, contact: Greg P. Thomas, Office of Continuing Medical Education, 2300 K Street, N.W., Washington, DC 20037; (202) 994-4285.

JOB ANNOUNCEMENT

The Hematology and Oncology Section of the Department of Internal Medicine and the Arizona Cancer Center are seeking a full-time tenure track faculty member at the assistant or associate professor level to develop a program in clinical immunology and biological therapy of cancer and allied diseases. The candidate must have the M.D. or M.D. plus Ph.D. degrees and be board eligible or certified in internal medicine and medical oncology or hematology/oncology. The candidate must have experience in clinical and laboratory immunology or a related area of science and in clinical trials of biological therapy. Experience in hematology is also highly desired.

Interested candidates should contact:

Evan M. Hersh, M.D.
Arizona Cancer Center
1501 N. Campbell Avenue
Tucson, Arizona 85724
602-626-2250

*The University of Arizona is an equal opportunity,
affirmative action employer.*

DIRECTION INSERT

Immune Globulin Intravenous (Human) GAMMAGARD®

DESCRIPTION

Immune Globulin Intravenous (Human), GAMMAGARD® is a sterile, dried, highly purified preparation of immunoglobulin which is derived from the cold ethanol fractionation process and is further purified using ultrafiltration and ion exchange adsorption. When reconstituted with the appropriate volume of diluent, this preparation contains approximately 50 mg of protein per mL, of which at least 90% is gamma globulin. The reconstituted product contains approximately 1% sodium chloride, not more than 20 mg/mL glucose, not more than 0.2 g/dL PEG, and 0.3M glycine as a stabilizing agent. It has a pH of 6.8 ± 0.4 .

The manufacturing process for Immune Globulin Intravenous (Human), GAMMAGARD, isolates gamma globulin without additional chemical or enzymatic modification and the Fc portion is maintained intact. Immune Globulin Intravenous (Human), GAMMAGARD contains all the immunoglobulin G antibody activities which are present in the donor population. On the average, the distribution of IgG subclasses present in this product is the same as is present in normal plasma.¹ Immune Globulin Intravenous (Human), GAMMAGARD contains only trace amounts of IgM and IgA.

Immune Globulin Intravenous (Human), GAMMAGARD contains no preservative.

This product has been prepared from large pools of human plasma which was taken only from plasma units found to have normal levels of alanine aminotransferase (ALT). Each unit of plasma used in the manufacture of this product has been found to be nonreactive for HBsAg and HTLV-III antibody by FDA approved tests.

CLINICAL PHARMACOLOGY

Immune Globulin Intravenous (Human), GAMMAGARD contains a broad spectrum of IgG antibodies against bacterial and viral agents that are capable of opsonization and neutralization of microbes and toxins.

Peak levels of IgG are reached immediately after infusion of Immune Globulin Intravenous (Human), GAMMAGARD. It has been shown that IgG is distributed relatively rapidly between plasma and extravascular fluid until approximately half of the total body pool is partitioned in the extravascular space. A rapid initial drop in serum levels is, therefore, to be expected.²

As a class, IgG survives longer *in vivo* than other serum proteins.^{2,3} Studies show that the half-life of Immune Globulin Intravenous (Human), GAMMAGARD is approximately 24 days. These findings are consistent with reports of a 21 to 25 day half-life for IgG.^{2,3,4} The half-life of IgG can vary considerably from person to person, however. In particular, high concentrations of IgG and hypermetabolism associated with fever and infection have been seen to coincide with a shortened half-life of IgG.^{2,3,4,5}

INDICATIONS AND USAGE

Antibody Deficiency

Immune Globulin Intravenous (Human), GAMMAGARD is efficacious in the treatment of primary immunodeficient states in which severe impairment of antibody forming capacity has

been shown, such as: congenital agammaglobulinemias, common variable immunodeficiency, Wiskott-Aldrich syndrome, and severe combined immunodeficiencies.^{4,5}

Immune Globulin Intravenous (Human), GAMMAGARD is especially useful when high levels or rapid elevation of circulating gamma globulins are desired or when intramuscular injections are contraindicated.

CONTRAINDICATIONS

None known.

WARNINGS

Immune Globulin Intravenous (Human), GAMMAGARD should only be administered intravenously. Other routes of administration have not been evaluated.

Immune Globulin Intravenous (Human), GAMMAGARD contains very low quantities of IgA (not more than 10 µg/mL) and although no instances of anaphylaxis associated with the use of this product have been observed during the clinical trials, such reactions have been observed with other immunoglobulin products.^{5,6} Immune Globulin Intravenous (Human), GAMMAGARD should be given with caution to patients with antibodies to IgA or selective IgA deficiencies.

PRECAUTIONS

Drug Interaction

Admixtures of Immune Globulin Intravenous (Human), GAMMAGARD with other drugs have not been evaluated. It is recommended that Immune Globulin Intravenous (Human), GAMMAGARD be administered separately from other drugs or medication which the patient may be receiving.

Pregnancy Category C

Animal reproduction studies have not been conducted with Immune Globulin Intravenous (Human), GAMMAGARD. It is also not known whether Immune Globulin Intravenous (Human), GAMMAGARD can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Immune Globulin Intravenous (Human), GAMMAGARD should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

The incidence of untoward reactions to Immune Globulin Intravenous (Human), GAMMAGARD is low, although various minor reactions, such as headache, fatigue, chills, backache, lightheadedness, fever and nausea may occasionally occur. The incidence of these reactions during the clinical trials was less than 6%. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Immediate anaphylactic and hypersensitivity reactions due to previous sensitization, although they have not been observed during the clinical trials, are a possibility. Epinephrine should be available for treatment of any acute anaphylactoid reaction. (See WARNINGS.)

DOSAGE AND ADMINISTRATION

Antibody Deficiency

For patients with primary immunodeficiencies, monthly doses of at least 100 mg/kg are recommended. Initially, patients may receive 200-400 mg/kg. As there are significant differences in the half-life of IgG among patients with primary immunodeficiencies, the frequency and amount of immunoglobulin therapy may vary from patient to patient. The proper amount can be determined by

monitoring clinical response and/or the serum IgG levels before each dose, to insure that they do not drop below 500 mg/dL.

Rate of Administration

It is recommended that initially a rate of 0.5 mL/kg per Hr be used. If infusion at this rate causes the patient no distress, the administration rate may be gradually increased but should not exceed 4 mL/kg per Hr.

A rate of administration which is too rapid may cause flushing and changes in pulse rate and blood pressure. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Administration

Immune Globulin Intravenous (Human), GAMMAGARD should be administered as soon after reconstitution as possible. Administration should not begin more than 2 hours after reconstitution.

The reconstituted material should be at room temperature during administration.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Follow directions for use which accompany the administration set. If a Hyland set is not used, make sure the administration set contains an adequate filter.

How Supplied

Immune Globulin Intravenous (Human), GAMMAGARD is supplied in either 2.5 g or 5.0 g single use vials. Each vial of Immune Globulin Intravenous (Human), GAMMAGARD is furnished with a suitable volume of Sterile Water for Injection, USP, a transfer device and an administration set which contains an integral airway and a 15 micron filter.

Storage

Immune Globulin Intravenous (Human), GAMMAGARD should be stored under ordinary refrigeration, (2 to 8 °C, 36 to 46 °F). Freezing should be avoided to prevent the diluent bottle from breaking.

The efficacy of an IGIV depends on the process used to make it.

GAMMAGARD® Immune Globulin Intravenous (Human)

Efficacy from an Immune Globulin Intravenous (IGIV) depends on many closely-linked factors. To function best, the entire IgG molecule should be undamaged—that is, intact. This lets the Fab portion bind antigens and the Fc section—the base of the “Y”—interact with a monocyte’s Fc receptors. These capabilities are, in large part, what enables IgG to mediate phagocytosis.

A recent study compared the ability of various IGIVs to bind with human monocyte Fc receptors.

Those isolated by DEAE-Sephadex purification conserved the capacity of IgG to interact with Fc receptors¹. One product preserved more of this capacity than all other preparations tested: GAMMAGARD® IGIV, which is produced by Travenol’s patented DEAE-Sephadex adsorption method. When your immunocompromised patients need an IGIV, specify GAMMAGARD® IGIV.

Consider: Thousands of Patients

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Burroughs Wellcome Co.
3030 Cornwallis Road
Research Triangle Park, NC 27709

Patients Rescued

WELLCOVORIN[®] TABLETS

== (leucovorin calcium) ==

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.¹

¹Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS (leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B₁₂. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g., methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below $5 \times 10^{-8} M$.^{1,2}

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e., trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.^{3,4,5}

THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

**You can help us
raise the colorectal
cancer cure rate.**

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces
cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

- Announcements 602
- Information for Contributors xiii, xiv

Effective January 1, 1987, all manuscripts submitted to **BLOOD** and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in **BLOOD** should be sent to: John W. Adamson, MD, Editor, **BLOOD**, University District Building—Room 410, 1107 NE 45th St, Seattle, WA 98105. Telephone: (206) 545-8080.

Please note that a processing fee of \$50.00 must accompany each manuscript submitted for publication in **BLOOD**.

The American Society of Hematology certifies that the continuing medical education offering provided by **BLOOD**, *The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

B CELL ACTIVATION GOT YOU PUZZLED?

COULTER HAS THE SOLUTION.

Our three new B cell markers make it possible to study B cell ontogeny from pre-B stem cells to plasma cells. B5 and B6 (CD23) are found on activated B cells, and not on resting B cells. The wide expression of the B5 antigen on B cell malignancies provides evidence for the hypothesis that all B cell malignancies are derived from subpopulations of activated B cells. B3 (CD22) is clearly unique: B3 is expressed on some pre-B cells, approximately 75% of resting B cells, and is lost with activation. Expand your research on AIDS, autoimmune diseases, and lymphoproliferative disorders with this complete series of B cell monoclonals. For more information, call 1-800-327-3778 (in Florida, 1-800-432-6518, Ext. 6880). Ask us about our complete line of monoclonal antibodies and support products.

ASK US FOR YOUR FREE B CELL ANTIGEN EXPRESSION WALL CHART.

Now You Can STORE LEUKOPOOR RED CELLS

...WITH THE CUTTER LEUKOTRAP™ RED CELL STORAGE SYSTEM.

Now you can cost-effectively produce and store high-quality leukopoor red cells for 42 days. The Leukotrap closed system efficiently removes leukocytes from fresh red cells, then maintains red cell viability for 42 days in the Nutricel® AS-3 additive solution.

MOST EFFICIENT CLOSED SYSTEM METHOD

The Leukotrap Storage System removes 91.4% of leukocytes and 80% of platelets, while recovering 90% of the red cells.*

Leukotrap's closed blood bag system contains an in-line leukocyte removal filter.

SIMPLE, RELIABLE PROCEDURE

The Leukotrap System provides consistent results with only minimal technician time and a standard centrifuge.

Provide a better red cell product with the Leukotrap Storage System...another Component Enhancement Product, only from Cutter.

For more information, contact your Cutter Biological Representative or call our Professional Services Dept. at (800) 527-7200; in CA (800) 527-7222.

AN ESSENTIAL PART OF YOUR COAGULATION WORKUP

THROMBO- WELLCOTEST® THE #1 FDP TEST

A comprehensive coagulation workup isn't complete without a rapid, reliable FDP assay. That's why leading laboratories turn to THROMBO-WELLCOTEST — the #1 choice for FDP testing. THROMBO-WELLCOTEST is from Wellcome Diagnostics, so its consistent high quality is assured. And it's backed by a highly competent technical staff.

LET OUR TEAM WORK WITH YOUR TEAM

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to *BLOOD*. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: *BLOOD* will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the *BLOOD* Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared

in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in *BLOOD* represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a \$50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to *BLOOD* and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of *BLOOD* will assume that the authors of research papers published in *BLOOD* are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and two complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least ⅛ inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in *BLOOD* can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of *BLOOD* should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the *BLOOD* office.

TWO-COLOR ANALYSIS: COULTER HAS THE SOLUTION.

Our four new dual assays are ideal for reducing preparation and analysis time for screening panels in lymphocyte phenotyping. Selected combinations of monoclonal antibodies offer the maximum in clinical relevance, ease of use, and cost savings. We have available combinations for enumeration of T and B cells, helper/suppressor cells, helper cell subsets, and T3/13 for the identification of states of T lymphocyte activation.

- **OPTIMAL FORMULATIONS:** Proprietary manufacturing techniques yield clean results with little or no background.
- **CLINICALLY RELEVANT COMBINATIONS:** These particular dual color assays offer the most clinically relevant combinations.
- **MAJOR TIME SAVINGS:** Dual assays reduce overall technical labor time by half.
- **READY TO USE:** No centrifugation required for these liquid reagents, optimally titrated and conjugated.

To order, call 1-800-327-3778 or 1-800-432-6518, Ext. 6880 from Florida.

Edited and with contributions by *David G. Nathan, MD*, Physician-in-Chief, The Children's Hosp., Robert A. Stranahan, Prof. of Pediatrics, Harvard Medical School, Boston, MA; and *Frank A. Oski, MD*, Pediatrician-in-Chief, The Johns Hopkins Children's Ctr.; Given Prof. of Pediatrics; Chairman, Dept. of Pediatrics, The Johns Hopkins Univ. School of Medicine, Baltimore, MD. With 63 contributors. Over 1855 pp. Over 445 ills. July 1987. 2-Vol. set: \$160.00. W6659-0.

*Review from a previous edition.

Now in a new edition, **HEMATOLOGY OF INFANCY AND CHILDHOOD** gives you the vast amount of information you need to stay on top of advances in this exciting field . . . accurate, authoritative information that **completely details the clinical manifestations and therapy of pediatric hematologic disorders**. Newly revised and expanded, this third Edition includes **basic science material and case studies** that hematologists, family physicians, and pediatricians can use in day-to-day practice.

This classic text covers all aspects of its complex subject, including physiology of the blood and blood forming organs, biochemistry, cellular biology, clinicopathologic correlations, treatment (and in some cases treatment complications), and clinically manifestations for more areas of pediatric hematology than any other text. Hundreds of vivid illustrations and tables guide you through the text and highlight key concepts. A handy appendix and a glossary and index provide ready reference.

Radiogenic mucositis or herpes simplex?

See answer under flap. ►

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

**When the problem begins with a virus,
end it with an antiviral.**

**The diagnostic
challenge in
immunocompromised
patients...**

Please see following page for brief summary of prescribing information.

ZOVIRAX® I.V. (acyclovir sodium) STERILE POWDER / I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M² every 8 hours (750 mg/M²/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.^{1,2,3}

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.⁴

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.⁵

Diagnosis
